About the Institute

The Hunt Institute for Botanical Documentation, a research division of Carnegie Mellon University, specializes in the history of botany and all aspects of plant science and serves the international scientific community through research and documentation. To this end, the Institute acquires and maintains authoritative collections of books, plant images, manuscripts, portraits and data files, and provides publications and other modes of information service. The Institute meets the reference needs of botanists, biologists, historians, conservationists, librarians, bibliographers and the public at large, especially those concerned with any aspect of the North American flora.

Hunt Institute was dedicated in 1961 as the Rachel McMasters Miller Hunt Botanical Library, an international center for bibliographical research and service in the interests of botany and horticulture, as well as a center for the study of all aspects of the history of the plant sciences. By 1971 the Library's activities had so diversified that the name was changed to Hunt Institute for Botanical Documentation. Growth in collections and research projects led to the establishment of four programmatic departments: Archives, Art, Bibliography and the Library.

On the Development of the Spores of
Helminthostachys zeylanica.

BY

RUDOLF BEER, B.Sc.

With Plates XI and XII.

THE writings of Goebel¹, Holtzman², Campbell³, and Bower⁴ have made us familiar with the early history of the sporangium of the Ophioglossaceae. The actual structure of the spore, however, and the later stages of development, leading up to the establishment of that structure, have, hitherto, only been very imperfectly described for any member of this Order. Recently the publication of two papers, by Cardiff⁵ and Stevens⁶ respectively, have added considerably to our knowledge of certain stages in the history of the spores of *Betrychium*, but we are still far from having a complete account of even this genus.

Through the kindness of Prof. F. W. Oliver I have had the opportunity of examining a number of fertile spikes of *Helminthostachys zeylanica* which had been preserved in spirit.

Although many important cytological details can only be determined with certainty by the study of material which has been specially fixed for the purpose, it was thought that the following notes might not be without their interest.

The first stages in the development of the sporangium of *Helminthostachys zeylanica* have been followed by Bower, who found the sporangium to be derived from a single superficial cell.

The first periclinal division of the cell defines the sporogenous from the protective portions of the sporangium; 'the sporogenous mass

⁵ Cardiff, 'Development of Sporangium in *Betrychium*,' Bot. Gazette, May 1905, vol. xxxix.

⁶ Stevens, 'Spore Formation in *Betrychium Virginianum*,' Annals of Botany, October 1905, vol. xix.

increases rapidly in bulk, whilst the cells surrounding the sporogenous mass, to the extent of several layers, assume the character of a tapetum which gradually becomes disorganised; finally the sporogenous cells separate and the majority of them divide into tetrads; but a considerable portion of them, scattered throughout the sporogenous mass, become disorganised without undergoing division; this is similar to what has been observed in the case of *Ophioglossum*¹.

My own observations begin with a stage at which the sporogenous cells have reached their full number, but in which the tapetum has not yet become disorganized (Pl. XII, Fig. 15). The tapetal layer is composed of radially elongated cells many of which have divided once or, more rarely, twice by periclinal divisions (Pl. XI, Fig. 1, and Pl. XII, Fig. 15). In *Botrychium* Cardiff observed periclinal divisions to follow one another until the tapetum became four or five cells in thickness. Stevens, however, does not confirm this statement and finds the tapetal layer of *B. virginianum* to be, as a rule, two cells in thickness, which would be more nearly in accordance with what I have seen in *Helminthostachys*.

The membranes of the tapetal cells are delicate, but clearly give the reactions of both cellulose and pectose. In this feature the tapetum of *Helminthostachys* apparently differs from that of *Botrychium*, in which Stevens found each tapetal cell to be 'delimited by a plasmatic membrane merely'. Although Cardiff does not actually describe the cell-walls of the tapetum, his words certainly imply the occurrence of a cell-wall other than a plasmatic membrane.

The sporogenous cells which lie within the tapetal layer are mostly square or oblong cells which measure about 12–18 μ across (Figs. 16 and 17). Their walls give the characteristic pectic reactions, but neither cellulose nor callose is to be found in them. The cytoplasm of these cells is fairly dense and contains a number of plastids usually crowded with starch. In slightly older sporangia the tapetal walls begin to break down, and in these disorganizing membranes I no longer succeeded in obtaining the cellulose reactions, although pectose was still clearly demonstrable².

The cytoplasm derived from the disorganized cells flows together (Figs. 2 and 16) and increases in amount, whilst the nuclei, which are mostly gathered together in little nests or groups at the inner or outer periphery of the tapetal layer, have become more numerous. The groups of nuclei are no doubt partly formed by the approximation of nuclei from several disorganized cells, but there can be little doubt that they also represent, to some extent, a number of daughter-nuclei which have origin-

¹ Spore-producing members, Part II, 1896, p. 35.

² I state this fact for what it is worth, although the failure of the cellulose reactions may be due to the increased difficulty of demonstration rather than to the real absence of this substance.

ated from the amitotic division of one or more mother-nuclei. The occurrence of constricted nuclei, such as I have represented in Fig. 2, bears out this view. Neither here, nor at any subsequent stage, have I seen tapetal nuclei dividing by mitosis.

The tapetal cytoplasm at this stage contains a quantity of starch and, in iron-haematoxylin-bismarck-brown preparations, presents a finely vacuolated appearance.

Up to the present the sporogenous cells have been united together in one coherent mass, but now they show the first signs of separating from one another (Fig. 17). The separation takes place in 'blocks' quite comparable with those described by Cardiff in *Botrychium*¹. In *Helminthostachys*, as in *Botrychium*, the separation appears to take place approximately 'in the order in which the original walls were laid down in the archesporium and young sporogenous mass.' The nuclei of the sporogenous cells of *Helminthostachys* are still in the resting condition when the separation of the 'blocks' commences.

Delicate and undifferentiated as the walls of the sporogenous cells appear, they must nevertheless possess a greater complexity of structure than becomes apparent with our instruments, for during the process of the separation of the sporogenous cells from one another a middle lamella becomes mucilaginous and is finally dissolved, whilst a secondary thickening layer remains unaltered round each sporogenous cell. The entire sporogenous membrane, both before and after the mucilaginous alteration of the middle lamella, gives no other reactions than those of pectic bodies. If I understand Stevens correctly, he found the mother-cells of *Botrychium* to be demarcated from one another and from the tapetum by a delicate plasmatic membrane alone, but Cardiff's statements do not bear this out and it certainly does not apply to the mother-cells of *Helminthostachys*. The sporogenous cells now divide into the spore-tetrads.

In the first division of the spore-mother-cells the chromosomes (which presumably occur in the reduced number) are seen to be small in size and rather crowded upon the spindle (Fig. 3). I have not succeeded in accurately counting their number, but I should very roughly estimate this to be between forty and sixty. Stevens has not recorded the number of chromosomes which occur in *Botrychium*. The spindle was surprisingly well preserved in the alcohol material and could be seen to terminate in very sharp, almost acuminate apices at which no traces of centrosomes were ever observed. The spindle extends to the very periphery of the mother-cell and is free from any radiations at its poles (Fig. 4). The daughter-nuclei, resulting from the first division, have in some of my preparations a curiously flattened, almost hemispherical shape when viewed in profile² (Fig. 5). They appear, like those of *Botrychium*, to enter into a resting

¹ Cardiff, l. c., p. 342.

² Compare this with Stevens' Plate XXIX, Fig. 28.

stage before passing on to the second division. The spore-mother-cells do not divide simultaneously, but all stages of division can be found in one sporangium. A mother-cell with its nucleus in the prophase of the first division not uncommonly occurs side by side with one which has completed its second division and has already developed the tetrad- (special-mother-cell) walls. In *Botrychium* Cardiff found that the cells in the same 'block' are always in the same stage, but in *Helminthostachys* the separation of the mother-cells has, apparently, been more complete before they enter upon the meiotic divisions, so that they have reached greater independence from one another than is the case in *Botrychium*.

Bower found that a considerable proportion of sporogenous cells became disorganized without undergoing division. In *Botrychium* Cardiff found no such disorganization to occur, and my preparations of *Helminthostachys* are quite in accordance with his observations and show no abortion of mother-cells. When the two divisions of the mother-cell have been completed the four cells of the tetrad are enveloped by the tetrad-wall (special-mother-cell wall) (Fig. 18).

This membrane is very delicate and in this respect forms a striking contrast to the conspicuous tetrad-walls of nearly all the other plants that I have examined (e.g. *Riccia*, *Anthoceros*, *Lycopodiaceae*, *Osmunda* &c.). It gives the pectic reactions very clearly, whilst several times I obtained a rather faint violet-pink reaction with calcium-chloride-iodine solution. For some unexplained reason the calcium-chloride-iodine solution does not always produce the same result; the tetrad-wall in some cases colouring violet-pink, in others yellow.

While we may, therefore, conclude with certainty that this wall contains pectose, we must leave it undecided whether or not this substance is accompanied by cellulose¹. The young spore-membrane colours, although rather faintly, with bismarck-brown, methylene blue, and similar dyes, and appears to be more or less cuticularized from a very early stage. It is a new formation and is not derived from the transformation of the special-mother-cell wall, which can still be recognized outside the spore-membrane (Fig. 6). In the meanwhile the disorganization of the tapetal walls has become complete, whilst the tapetal cytoplasm, which now forms a sort of plasmodium around the sporogenous cells (Fig. 16), has increased considerably in amount. The numerous nuclei which it contains still tend to be aggregated in groups.

We now find the plasmodial envelope sending finger-like processes into the cavity of the sporangium between the separated sporogenous cells. These cytoplasmic processes spread further and further between the sporogenous cells, branching and anastomosing with one another and separating

¹ No other cellulose reaction, but only the inconstant appearance of the violet-pink colour with calcium-chloride-iodine, was given by these walls.

the young tetrads more and more completely from one another (Fig. 18). At first these plasmodial strands consist solely of cytoplasm, unaccompanied by nuclei, which remain in the peripheral envelope. Soon, however, we can observe the nuclei dipping into the broader arms of cytoplasm and making their way into the interior of the sporangial cavity. As the round or oval nucleus passes into the strand of cytoplasm it usually alters its shape and becomes drawn-out, often into a very fine point, at its anterior extremity (Fig. 7). It usually stains more deeply at this beak-like process than it does at its blunt, posterior end. As it moves further along the strand and passes between the spore-tetrads it not infrequently assumes an elongated form, sometimes almost justifying the term vermiform, until it temporarily comes to rest at this or that spot, when it reassumes a more iso-diametric shape. The tapetal plasma, which has a finely vacuolated structure in successful preparations, contains an abundant supply of starch. All the cells composing the walls of the sporangium are rich in starch; the membranes of these cells give the pectic and cellulose reactions. The spores remain associated together in groups of four throughout the greater part of their development. They now rapidly increase in size, but their walls remain very thin and the cytoplasm they enclose is scanty. In consequence of this the spores, at this stage, are nearly all collapsed in the alcohol material (Fig. 19). The young spores are tetrahedral in shape and the edges of those surfaces which adjoin one another in the neighbouring spores of a tetrad are raised up into ridges. In this way each spore develops three ridges upon its surface, and these ridges converge to a common point (Fig. 8, a).

Early in the history of the spore one can see that the sides of the tetrahedron which meet at the ridges are only very loosely joined together. The action of various reagents, and even the pressure of the microtome knife, often leaves the spore with three flaps entirely separated from one another at the ridges, as is shown in Fig. 8, b. The cuticularized wall of the spore now grows somewhat in thickness, and at about this time a new layer—the endospore—makes its appearance within it. This layer, which gives the reactions of a pectic body, can be traced as a continuous, although delicate, layer over the entire inner surface of the spore-wall.

In microtome sections which have passed through the apex¹ of the spore we can trace a little process or fold of the endospore which has pushed between the ridges of the exospore and which reaches to the outer surface (Fig. 9). In spores measuring about 23μ across their longest diameter the exospore has become sufficiently thick to prevent the collapse of the spore in alcohol. The surface of the spore is still smooth and its protoplast poor in substance².

¹ Viz., the point at which the three ridges meet.

² It usually contains a very little starch, however.

The further growth in thickness of the exospore continues to leave the fold of endospore uncovered at the apex of the spore. The smooth surface of the exospore now becomes slightly wavy in outline, and this soon leads to the formation of the reticular sculpture which is characteristic of the mature spore.

The fully grown spore measures, in section, about 33μ by 28μ . The exospore is thicker at the apex than over the rest of the spore, but is perforated by a cleft through which the fold of endospore reaches the exterior. This cleft is particularly well seen after treatment with a mixture of sulphuric and chromic acids or with sulphuric acid alone, but it can be quite readily distinguished in sections which have been stained with methylene blue, or bismarck-brown without the previous action of acid. Chlor.-zinc-iodine solution, to which more iodine than usual has been added, also very clearly shows the endospore—coloured brown—penetrating the exospore and reaching the exterior. The reticular sculpturing upon the surface of the exospore appears in section as a series of blunt processes with flattened summits (Figs. 10 and 11). The protoplast of the spore has now become somewhat richer in substance and usually includes starch, but not in any quantity.

Nothing in the nature of an episporium is to be found in the spores of *Helminthostachys*. The exospore and, most probably, also the endospore are in the first place deposited by the secretory activity of the spore-protoplast. There is no possibility of the former layer being derived from the transformation of part or all of the mother-cell-wall, since this at all times very delicate wall can still be distinguished, in apparently undiminished thickness, over the surface of the young exospore (Fig. 6).

The fact that the exospore and endospore are inseparably united together at first suggests the probability of the two layers being derived from the differentiation of an originally single, homogeneous membrane. As Fitting¹ has already pointed out, however, the existence of a close fusion between two layers of a wall does not necessarily indicate their common origin by differentiation, and there are several well-known cases in which two lamellae are intimately bound together, but which unquestionably have been separately deposited by the cell-protoplast. In the present instance, moreover, it is difficult to understand how a cuticularized membrane can be so differentiated as to give rise to a pure pectic lamella on one of its faces. The development of the little fold of endospore at the apex of the spore is also more readily explained as a new formation than as a product of differentiation. Shortly after the exospore has been formed round the young spore and throughout the time that this layer is growing in thickness and in surface the tapetal plasmodium which envelops the spore-tetrads shows unmistakable signs of metabolic activity.

¹ H. Fitting, Bot. Zeitung, Bd. LVIII, 1900, p. 126.

It is impossible to escape the conclusion that this metabolism is concerned with the elaboration of material for the growth of the exospore. That such material must be forthcoming is of course obvious, and the two sources to which one naturally looks for this supply are the spore-protoplast on the one hand and the tapetum upon the other. In *Helminthostachys* (at least in my spirit material) the spore protoplast, after the first formation of the exospore, is very poor in substance, and it is very unlikely that it can furnish sufficient plastic material for the growth of the wall. When one turns to the tapetum, however, one finds here a gradual utilization of reserve-materials which can fully account for the substance which is being employed in the growth of the exospore. Moreover, if we deny that the tapetal material is being utilized for this purpose it is not easy to see what the fate of this substance may be. The growth of the wall of the sporangium is amply provided for by the reserve-materials contained in its cells, whilst the protoplasts of the spores do not increase in size or substance during this time, so that we are driven to associate the disappearance of starch and cytoplasm from the tapetum with the only other demonstrable utilization of material, viz., that which is adding to the size and thickness of the spore-coats.

It is impossible at present, however, to decide whether the material elaborated in the tapetum is directly built up in the spore-walls or whether it first passes, in a liquid form, into the spore-protoplast which, either with or without further elaboration, distributes it to the walls.

In view of the important part that the tapetal plasmodium plays in the growth of the spore-walls it will be necessary at this point to look more closely at its appearance and behaviour. We find that starch is abundant in the tapetal cytoplasm before the walls of the tapetum disorganize and that it continues to exist there in considerable quantities until the period during which the exospore undergoes its most active growth in thickness. During this time the tapetal plasma is either very poor in starch or, more often, this substance is quite absent from it. When the exospore has completed its growth in thickness and the spore-protoplast is about to add to its substance, starch can usually again be seen in the tapetal cytoplasm but never in quantities that can compare with those which occurred in the early stages of sporangial development.

The tapetal cytoplasm at first increases somewhat in amount (immediately after the disorganization of the tapetal cells), but during the later history of development it slowly but steadily decreases in quantity (compare Figs. 18, 19, and 20). Where it abuts upon a vacuole (such as that which encloses a spore or spore-tetrad) the cytoplasm has a very clearly marked plasmatic membrane; elsewhere it is finely vacuolated in structure. It is the vacuolar cytoplasm which is gradually utilized in the metabolic processes of the plasmodium, and the plasmatic membranes,

which limit neighbouring vacuoles in consequence approach one another more and more closely. In sporangia, shortly before their dehiscence, the vacuolar cytoplasm has almost completely disappeared, but the plasmatic membranes are still present between the spores (Fig. 20). These can then, in nearly all cases, be seen to be double in structure owing to the complete approximation of the plasmatic membrane of adjoining vacuoles¹. Starch grains can not infrequently be seen flattened out between the two adpressed membranes and, at the angles formed by the meeting of several vacuoles, nuclei occur.

The nuclei show, at all stages, considerable variation in size, in form, and in character. In *Botrychium* Cardiff found that the nuclei underwent a very considerable increase in size during development; thus in young sporangia he gives their size as 8μ , whilst at a later stage he found them to measure $15-20\mu$. In *Helminthostachys* the general average of size of the tapetal nuclei appears to remain about the same at different periods of development.

- | | |
|--|------------------------|
| (a) Tapetal cells still intact | = $13 \times 11\mu$ |
| (b) Young spores with thin, smooth exospore | = $13.4 \times 10\mu$ |
| (c) Spores with immature sculpturing on exospore | = $12.6 \times 9.6\mu$ |
| (d) Spores just before dehiscence of sporangium | = $13 \times 11\mu$ |

The above figures are the averages calculated from a large number of countings and they show practically no alteration in the size of the tapetal nuclei.

The form of the nuclei is very various. In the tapetal cells before disorganization and in the tapetal plasmodium before this flows between the sporogenous cells the nuclei are more or less oval in shape. The peculiar alteration in form which they often undergo as they pass within the sporangial cavity has already been described. In the later periods of development these nuclei are sometimes oval or spherical in outline; often they are irregular in shape and occasionally their form is angular (Fig. 12). They possess, in most cases, a distinct nuclear membrane and are usually rich in chromatin; several nucleoli can generally be seen in each nucleus. The chromatic granules are often closely packed (and the nucleus in consequence deep-staining) in the smaller nuclei, whilst in the larger nuclei the chromatin-grains are frequently separated more widely from one another and the nucleus contains more non-staining material.

In *Botrychium* Cardiff found that 'as the spores commence to separate in the tetrad, the tapetal cytoplasm has entirely filled the sporangium and many of the nuclei have begun to disorganize, though they seem unusually persistent and many are found after the tetrad is fully formed. Later,

¹ In consequence of the entire disappearance of the vacuolar cytoplasm which separated them from one another at an earlier stage.

when the spores are entirely separated and mature, the tapetum disappears.' In *Helminthostachys* the tapetum and tapetal nuclei are evidently more persistent than Cardiff found to be the case in *Botrychium*¹. It has already been mentioned that the plasmatic membranes and many nuclei are still to be found between spores which are quite or nearly mature, and I have rarely found nuclei which were degenerating except in sporangia which were almost ready to dehisce. In such sporangia the majority of the nuclei stained intensely and were closely packed with chromatic granules, whilst here and there a nucleus was seen in which the nuclear membrane had disappeared and the granules were becoming dispersed (Fig. 13). Mitotic divisions of the tapetal nuclei were at no time seen.

Cardiff records frequent amitotic divisions of the tapetal nuclei of *Botrychium*, but Stevens was unable to confirm this observation.

In *Helminthostachys* I have found reason to believe that in the early stages of sporangial development, immediately after the tapetal membranes have disintegrated, the nuclei do multiply by direct division, but in older sporangia it is much more difficult to find any evidence of such divisions. Irregularities in outline, which sometimes lead to a more or less constricted shape, not uncommonly occur, but most of these are undoubtedly to be referred to those passing changes of form which are so frequently to be found in nuclei that are taking part in active metabolic processes. Occasionally these changes of form may actually lead to a division of the nucleus, but in my material this is certainly rare. An isolated instance of such a division is shown in Fig. 14. Very possibly the conditions which prevail at the time when the material is collected may exert an influence upon the tapetal nuclei and may explain the differences which occur in the accounts of Cardiff and Stevens.

The principal features, therefore, which the tapetal plasmodium presents during the period of exospore growth are (a) an almost or quite complete disappearance of starch, (b) a gradual diminution of the finely vacuolar cytoplasm, and (c) the richly chromatic nuclei which often show irregularities of outline.

These features, I think, bear out the view already expressed that the tapetal plasmodium is the centre of metabolic activities in which a substance is elaborated from the raw materials contained in the tapetum. For reasons already stated we may further conclude that this substance is, directly or indirectly, employed in the growth of the spore-wall.

¹ Stevens also records much greater persistence of the nuclei in the *Botrychium* examined by him.

from having a complete account ^{of} even of this genus.

Through the kindness of Prof. F.W. Oliver I have had the opportunity of examining a number of fertile spikes of Helminthostachys Zealanica which had been preserved in Spirit.

Although many important cytological details can only be determined ^{with certainty} by the study of material which has been specially fixed for ~~the~~ purpose it was thought that the following notes might not be without their interest.

The first stages in the development of the Sporangium of Helminthostachys Zealanica have been followed by Bowers who found the Sporangium to be derived from a single superficial cell.

The first periclinal division of the cell defines the Sporogenons from the protective portions of the Sporangium; "the Sporogenons

" mass increases rapidly in bulk, whilst the
 " cells surrounding the Sporogenous mass, to the
 " extent of several layers, assume the character
 " of a tapetum which gradually becomes
 " disorganised; finally the sporogenous cells
 " separate & the majority of them divide into
 " tetrads; but a considerable portion of them,
 " scattered throughout the Sporogenous mass
 " become disorganised without undergoing
 " division; this is similar to what has been
 " ~~described~~ observed in the case of Ophiodopsis⁽¹⁾

My own observations begin with a stage at
 which the Sporogenous cells have reached their
 full number but in which the tapetum
 has not yet ~~to~~ become disorganised (^{Fig 15} ~~Photo~~)

~~The tapetal layer is composed of radially
 elongated cells which ^{usually} have divided once
 or twice by periclinal divisions. Each cell
 of the tapetum ~~appears to be~~ uni-nucleate
 or occasionally bi-nucleate~~

The tapetal layer is composed of radially elongated cells many of which have divided once or, more rarely, twice by periclinal divisions ^{(figs 1 + 7¹⁵) (at right)}. In Botrychium Cardiff observed periclinal divisions to follow one another until the tapetum became four or five cells in thickness. Stevens, however, does not confirm this statement + finds the tapetal layer of B. virginianum to be as a rule two cells in thickness which ~~conjugate~~ ^{would be more nearly} in accordance with what I have seen in Helminthostachys.

The membranes of the tapetal cells are delicate but clearly give the reactions of both cellulose + pectose. In this feature the tapetum of Helminthostachys apparently differs from that of Botrychium in which Stevens found each tapetal cell to be "delimited by a plasmatic membrane merely". Although Cardiff does not actually describe the cell-walls of the tapetum ~~as certainly~~ his words certainly imply the occurrence of a cell-wall other than a plasmatic membrane.

a good deal of starch.
 + ~~the~~ includes only scanty cytoplasm but
 the ^{membranes} ~~walls~~ of these cells are delicate +
 give the reactions of both pectose + cellulose.

The sporogenous cells which lie within the tapetal layer are mostly square or oblong cells which measure about 12-18 μ across ^(Photo 16.114). Their walls give the characteristic pectic reactions but neither cellulose nor callose is to be found in them. The cytoplasm of these cells is fairly dense + contains a number of crowded plastids usually ~~filled~~ with starch.

In slightly older sporangia the tapetal walls begin to break down + in these disorganising membranes I ~~was not~~ ^{no longer} succeeded in obtaining the cellulose reactions although pectose was still clearly demonstrable.⁽¹⁾

The cytoplasm derived from the disorganised cells flows together ^(Photo 16.115) + increases in amount whilst the nuclei, ~~become much more~~ ^{which are mostly gathered}

(1) I state this fact for what it is worth although the failure ~~of the cellulose reactions~~ may be due to the increased difficulty of demonstration rather than to the real absence of the substance.

together in little nests or groups at the inner or outer periphery of the tapetal layer, have become more numerous. The groups of nuclei are no doubt partly formed by the approximation of nuclei from several disorganised cells but I there can be little doubt that they also represent, to some extent a number of daughter-nuclei which have originated from the amitotic division of one or more mother-nuclei. The occurrence of constricted nuclei, such as I have represented in Fig 2 bears out this view. Neither here,

nor at any subsequent stage, have I seen tapetal nuclei dividing by mitosis. The tapetal cytoplasm at this stage contains a quantity of starch + in iron-haematoxylin-bismarck brown preparations presents a finely vacuolated appearance.

Up to the present the sporogenous cells have been united together in one

coherent mass but now they show the first signs of separating from one another. ^(Pl. Fig. 17) The separation takes place in "blocks" quite comparable with those described by Cardiff in Botrychium". In Helminthostachys, as in Botrychium, the separation appears to take place approximately "in the order in which the original walls were laid down" in the archesporium + young sporogenous mass". The nuclei of the sporogenous cells of Helminthostachys are still in the resting ~~stage~~ condition when the separation of the "blocks" commences.

Delicate + undifferentiated as the walls of the sporogenous cells appear they must nevertheless possess a greater complexity of structure than becomes apparent with our instruments for during the process of the separation of the sporogenous cells from one another a middle

~~Cardiff, I.D. "Development of sporangium in Botrychium"~~

~~Bull. Belg. XXXIX May 1905 p. 342~~
 (1) Cardiff l.c. p. 342

lamella becomes mucilaginous + is finally dissolved whilst a secondary thickening layer remains unaltered round each sporogenous cell. The entire sporogenous membrane, both before + after ~~to~~ the mucilaginous alteration of the middle lamella gives no other reactions than those of pectic bodies. If I understand Stenens correctly he found the mother-cells ^{of Botrychium} ~~to~~ [^] be demarked from one another + from the tapetum by a delicate plasmatic membrane alone but Cardiff's ^{statements} ~~observations~~ do not bear this out + it certainly does not apply to the mother-cells of Helminthostachys. The sporogenous cells now divide into the spore-tetrads.

In the first division of the spore-mother cells the chromosomes (which presumably occur in the reduced number) are seen to be small in size & rather crowded upon the spindle ^(Fig. 3.) ~~very numerous~~. In spite of repeated attempts I have not succeeded in accurately counting their number & neither, apparently, has Stenens done so in the case of Botrychium.

I have not succeeded in accurately counting their number but I should ^{very} roughly estimate this to lie between 40 + 60. Stevens has not recorded the number of chromosomes which occur in Botrychium. The spindle was surprisingly well preserved in the alcohol material & could be seen to terminate in a very sharp, almost acuminate apices at which no traces of centrosomes were ever observed. The spindle extends to the very periphery of the mother cell & is free from any radiations at its poles (Fig 4). ~~The daughter nuclei appear to pass through a resting stage, like those of Botrychium.~~ The daughter-nuclei, resulting from the first division, have in some of my preparations a curiously flattened, almost hemispherical shape when viewed in profile. ⁽¹⁾ (Fig 5). They appear, like those of Botrychium, to enter into a resting stage before passing on to the second division.

(1) compare this with Stevens' Plate XXIX Fig 28.

The spindle was ~~very clearly~~ surprisingly well preserved in the alcohol material & could be seen to terminate in a very sharp, almost acuminate, apices at which no traces of centrosomes were ever observed. The spindle extends to the very periphery of the mother-cell & is free from any radiations at its poles.

The Spore-mother cells do not ~~divide~~ divide simultaneously ~~in a sporangium~~ but all stages of division can be found in one sporangium: a mother-cell with its nucleus in the prophase of the first division not uncommonly occurs side by side with one which has completed its second division & has already developed the tetrad- (special-mother-cell) walls.

In Botrychium, Cardiff found, that the cells in the same "block" are always in the same stage but in Helminthostachys the separation of the mother cells has, apparently,

been more complete before they enter upon the meiotic divisions so that they have reached greater independence from one another than is the case in Botrychium.

Bower found that a considerable proportion of sporogenous cells became disorganised without undergoing division. In Botrychium Cardiff found no such disorganisation to occur & my preparations of Helminthosclerops are quite in accordance with his observations & show no abortion of mother-cells.

When the two divisions of the mother-cell have been completed the ~~tetrad~~ four cells of the tetrad are enveloped by the ^(Fig 18) ~~phloem~~ ~~tetrad-wall~~ (special-mother cell wall). ~~This membrane is~~
~~very difficult to demonstrate clearly as it is extremely~~ delicate & is readily confused with the proper spore-membrane which makes its appearance at an ~~early~~ early period.
~~The clearest differentiation between mother cell~~

This membrane is very delicate & in this respect forms a striking contrast to ~~the~~ ^{the} conspicuous ~~the~~ ^{the} massive tetrad-walls of nearly all the other plants that I have examined (e.g. of Riccia, Anthoceros, Lycopodiaceae, Osmunda ^{etc.}) ~~pollen mother-cells of Angiosperms or Gymnosperms~~

It gives the pectic reactions ^{very} clearly whilst several times I obtained a rather faint ~~cellulose~~ ^{violet-} ~~pink~~ reaction with calcium-chloride - Iodine solution.

~~The latter reaction was however inconsistent & uncertain not always to be detected~~

For some, unexplained, reason ^{the} calcium-chloride-iodine solution ^{does} ~~not~~ not always produce the same result; the tetrad-wall in some cases colouring violet-pink in others yellow.

~~I conclude, therefore, that whilst this wall is certainly contains pectose in it this is probably associated with cellulose which is more or less masked by it must remain undecided whether this is associated with cellulose or not.~~

Whilst we may, therefore, conclude with certainty that this wall contains pectose we must leave it undecided whether or not this substance is accompanied by cellulose⁽¹⁾.

The young spore-membrane colours, ^{although} rather faintly, with bismarck-brown, ^{& similar dyes} melting blue, ~~etc.~~ appears to be more or less cuticularised from a very early stage, ~~if not from its very first appearance.~~ It is a new formation & is not

derived from the transformation of the special-mother-cell wall which ~~it~~ can still be recognised outside the spore-membrane. (Fig 6)

In the meanwhile the disorganisation of the tapetal walls has become complete whilst the tapetal cytoplasm, ~~has~~ which now forms a sort of plasmodium around the sporogenous cells, ^(Fig 16) has increased considerably in amount. The ~~are~~ numerous nuclei which it contains still tend to be aggregated in groups.

(1) No other cellulose reaction, but only the inconstant appearance of the violet-pink colour with Calcium-chloride-Iodine, was given by these walls. Solubility in cuprammonia was not tested.

~~There is some evidence to show that they are groups. & continue to show evident signs of occasionally undergoing mitotic divisions of amitotic division.~~

We now find the plasmodial envelope sending finger-like processes ^{into the cavity of the Sporangium} between the separated sporogenous cells.

These cytoplasmic processes spread further & further between the ^{sporogenous cells} ~~young tetrads~~ ^{branching} anastomosing with one another & separating the young tetrads more & more completely from one another (cp. Photo Fig 16). At first these

cytoplasmic strands consist solely of cytoplasm, unaccompanied by nuclei or ~~starch~~, which remain in the peripheral envelope. Soon, however, we can observe the nuclei dipping into the broader arms of cytoplasm & making their way into the interior of the Sporangial cavity.

~~As they pass into the process strands of cytoplasm the oval or round nucleus alters ^{their} shape & becomes drawn out~~

As the round or oval nucleus passes into the strand of cytoplasm it ^{usually} alters its shape & becomes drawn out, often into a very fine point, at its ^{anterior} ~~front~~ extremity.

(Fig 7) It usually stains more deeply at this beak-like process than it does at its blunt, posterior end. As it travels further along the strand & passes between the spore-tetrads it ^{not infrequently} assumes an elongated form, sometimes almost justifying the term vermiform, until it temporarily comes to rest at this or that spot when it re-assumes a more iso-diametric shape.

~~An abundant supply of starch is contained~~

+ The tapetal plasma, which has a finely vacuolated structure in successful preparations, contains an abundant supply of starch. All the cells composing the walls of the sporangium are rich in starch; the membranes of these cells give the pectic & cellulose reactions.

The spores remain associated together in groups of four throughout the greater part of their development. They now rapidly increase in size but ~~the thickness of their~~ their walls remain very thin & the cytoplasm they enclose is scanty. In consequence of this the spores, ~~short~~ at this stage, are nearly all collapsed in the alcohol material. The ^{young} spores are tetrahedral in shape & the edges of those surfaces which adjoin one another in the neighbouring spores of a tetrad are raised up into ridges. In this way each spore develops three ridges upon its surface & these ridges converge to a common point. (Fig 8a)

Early in the history of the spore one can see that the ~~surface~~ sides of the tetrahedron which meet at the ridges are ~~quite~~ only very loosely joined together. ~~as are actually free~~ ^{various} from one another. The action of ^{various} reagents & even

the pressure of the microtome knife often leave the spore with three flaps ^{entirely} separated from one another at the ridges as is ^{shown} ~~shown~~ in Fig 8b. The cuticularized wall of the spore ~~has~~ now grows somewhat ~~it~~ in thickness & ^{at about this time} a new layer - the ^{endospore} ~~outer~~ makes its appearance within it. This layer, which gives ~~all~~ the reactions of a pectic body, ~~is first seen just beneath the apex of the spore where the three ridges converge; it can be traced, however, as a~~ ^{can} be traced as a ~~continuous~~ continuous, although ~~extremely~~ delicate, layer over the entire inner surface of the spore wall.

In microtome sections ~~of the spore~~ which have passed through the apex ⁽¹⁾ of the spore we can trace a little process or fold of the endospore which ~~has~~ has pushed ~~spore~~ between the ridges of the exospore & which reaches to the outer surface. (Fig 9)

(1) viz. the point at which the three ridges meet.

In Spores measuring about 23μ across their longest diameter the exospore has become sufficiently thick to prevent the collapse of the Spore in alcohol. The surface of the Spore is still smooth & ~~the solid matter which it is contained in its protoplasmic~~ still poor in solid substance."

The further growth in thickness of the exospore continues to leave the ~~projection~~ fold of endospore uncovered at the apex of the spore. ~~the smooth surface of~~ the exospore now becomes slightly wavy in outline & this soon leads to the formation of the reticular sculpture which is characteristic of the mature Spore.

The fully grown Spore measures, in section, about ^{33μ} ~~32μ~~ by 28μ . The exospore ~~is~~ ^{has} become thicker at the apex than over the rest of the Spore but is perforated by a cleft through which the fold of endospore

(1) It usually contains ^{very} a little starch, ~~which~~ however.

~~Ractor~~ reaches the exterior. This cleft is particularly well seen after treatment with a mixture of Sulphuric + chromic acids or with Sulphuric acid alone but it can be quite readily distinguished in sections which have been stained with methylene blue or bismarck brown without ^{the} previous action of acid. Chlor-Zinc - iodine Solution, to which more iodine than usual has been added, also ^{Very clearly} shows the Endospore - coloured brown - penetrating the exospore & reaching the exterior. The reticular sculpturing upon the surface of the exospore appears in section as a series of blunt processes with flattened ^(Figs 10 + 11) summits. The protoplast of the Spore has now become somewhat richer in substance & usually includes starch but not in any quantity.

reaches the exterior. This cleft in the exospore is particularly well seen after treatment with dilute sulphuric acid but it can be quite clearly distinguished in sections which have been stained with methylene blue or bismarck brown without previously treating them with ^{the} acid.

Nothing ⁱⁿ of the nature of an epispore is to be found in the spores of Helminthostachys.

~~We have already seen that it has already been said that both the exospore & the endospore~~

~~both~~ ^{not probably also} the exospore & the endospore are in the first place deposited by the secretory activity of the spore-protoplast. There ^{is} ~~can~~ ^{no possibility} ~~be no~~ question of the former layer being derived from the transformation of part or all of the mother-cell wall since this, at all times very delicate ^{wall,}, can still be distinguished in apparently undiminished thickness, over the surface of the young exospore.

The fact that the exospore & endospore are inseparably united together, at first suggests the ^{probability} ~~possibility~~ of the two layers being derived from the differentiation of an originally single homogeneous membrane. As ~~for~~ Fitting⁽¹⁾ has already pointed out, however, the ~~existence~~ ~~fact~~ of a close fusion between two layers of a wall does not necessarily indicate their common origin by differentiation & there are several well known cases in which two lamellae are intimately bound together but ^{which} unquestionably have been separately deposited by the cell-protoplast.

In the present instance, moreover, it is difficult to understand how a cuticularised membrane can be so differentiated as to give rise to a pure pectic lamella on one of its faces. The ~~origin~~ development of the little fold of endospore at the apex of the spore is also more readily explained as a new formation than ^{as} a product of differentiation.

Shortly after the exospore has been formed round the young spore & throughout the time that this layer is growing in thickness & in surface the apical plasmodium which envelopes the spore-tetrads shows unmistakable signs

(1) Fitting, H. Bot. Zeitung Bd 58 1900 p. 126.

of metabolic activity. It is ^{impossible} ~~difficult~~ to escape the conclusion that this Metabolism is concerned with the elaboration of material for the growth of the exospore. That such material must

be forthcoming is of course obvious + the two ~~most natural~~ ^{naturally} sources to which one looks for this supply are the Spore-protoplast on the one hand + the tapetum upon the other.

In Helminthostachys (at least in my spirit material) the Spore-protoplast, after the first formation of the exospore, is very poor in substance + it is very unlikely that it can furnish sufficient plastic material for the growth of the wall. ^{When} One ~~next~~ turns to the tapetum, ^{however} ~~then~~ one finds ^{here} a gradual utilisation of reserve-materials which ^{can} ~~fully~~ ^{completely} account for the substance which is being employed in the growth of the exospore. Moreover, if we deny that the tapetal material is being utilised for this ^{purpose} ~~manner~~

(+) At least in my alcohol material the spore contains a little starch at all periods of development but there is no loss of this starch or a diminution of the always scanty cytoplasm during the time of exospore growth such as we should expect to find if the spore-protoplast were itself contributing material for this growth.

it is ^{not easy} difficult to see what the fate ^{of this substance} may be.
 The growth of the wall of the sporangium is
 amply provided for by the reserve-materials
 contained in its cells ^{whilst} the protoplasts of the
 spores do not increase in ~~amount~~ size
 or substance during this time so that we
 are driven to associate the disappearance of
 starch & cytoplasm from the tapetum with
 the only ^{other} demonstrable utilisation of material
 viz that which is ^{being} ~~contributing to the growth of the~~
~~built up in the substance~~
^{adding to the size & thickness of the}
~~of the growing sporangium~~ spore-coats.

It is impossible at present, however, to
 decide whether the material elaborated in the
 tapetum is directly built up in the spore-walls
 or whether it first passes ^{in a liquid form} into the spore-
 protoplast which, either with or without
 further elaboration, distributes it to the
 walls.

In view of the important part that the
 tapetal plasmodium plays in the growth of

the Spore-walls it will be necessary ^{at this point,} to look
 more closely at its appearance & behaviour.
 We find that Starch is abundant in the
 tapetal cytoplasm before the walls of the tapetum
 disorganise & that it continues to ~~be~~ exist
 there in considerable quantities until the period
 during which the exospore undergoes its most
 active growth in thickness. During this time
 the tapetal plasma is either very poor in starch
 or, more often, this substance is quite absent
 from it. When the exospore has completed
 its growth in thickness & the spore protoplast
 is about to add to its substance starch can
 usually again be seen in the tapetal cytoplasm
 but never in quantities that can compare with those
~~that~~ ^{which} occurred in the early stages of sporangial development.

^{tapetal}
 The cytoplasm at first increases somewhat
 in amount (immediately after the disorganisation
 of the tapetal cells) but during the sub-
 later history of development it slowly but
 steadily decreases in quantity ^(compare Plate 19 & 20). Where it
 abuts upon a vacuole (such as that which
 encloses a spore or spore-tetrad) ^{the cytoplasm} it has
 a very clearly marked ^{plasma-}membrane; ^{elsewhere} it is finely vacuolated in structure.
 It is the vacuolar cytoplasm which is
 gradually utilised in the metabolic processes
 of the plasmodium & ~~which~~ the plasma-
 membranes, ~~in consequence~~ which limit
 neighbouring vacuoles, ^{in consequence} approach one another
 more & more closely. In sporangia,
 shortly before their dehiscence, the vacuolar
 cytoplasm has almost completely disappeared
 but the ^{plasma-}membranes are still present
 between the spores ^(Plate 20). These can ^{then} in nearly all
 cases, be seen to be double in structure owing

to the complete approximation of the plasmatic-membranes of adjoining vacuoles". ~~Flattened in between these membranes~~ Starch grains can not infrequently be seen flattened out between the two adpressed membranes & at the angles formed by the meeting of several vacuoles, nuclei occur.

The nuclei show, at all stages, considerable variation in size, in form & in character.

In Botrychium Cardiff found that the nuclei underwent a very considerable increase in size during development; thus in young sporangia he gives their size as 8μ whilst at a later stage he found them to measure $15-20\mu$. In Helminthostachys the general average of size of the tapetal nuclei ~~may, perhaps, increase very slightly between the early & middle stages of development but this increase does not approach that which Cardiff recorded~~

(1) In consequence of the entire disappearance of the vacuolar cytoplasm which separated them from one another at an earlier stage.

~~It can have no great significance. The following figures give the average dimensions at different stages.~~

appears to remain about the same at the different periods of development.

- (a) Tapetal cells still ~~is~~ intact = $13 \times 11 \mu$
- (b) Young spores with thin smooth exospore = $13.4 \times 10 \mu$
- (c) Spores with immature sculpturing on exospore = $12.6 \times 9.6 \mu$
- (d) Spores just before dehiscence of sporangium = $13 \times 11 \mu$

Digitized by Hunt Institute for Botanical Documentation

The above figures are the averages calculated from a large number of countings & they show practically no alteration in the size of the tapetal nuclei.

~~It has already~~ The form of the nuclei is very various. In the tapetal cells before disorganization & in the tapetal plasmodium before this flows between the sporogenous cells the nuclei are more or less oval in shape. The peculiar alteration in form which they

often undergo as they pass within the sporangial cavity has already been described. In the later period of development these nuclei are sometimes oval or spherical in outline; ~~more~~ often they are irregular & ~~almost amoeboid~~ in shape, + ^{occasionally} ~~frequently~~ ^{blatly} their form is ~~slightly~~ angular. (Fig 12).

They possess, in most cases, a distinct nuclear-membrane & ~~have a granular structure~~. In the smaller nuclei ~~there are~~ chromatin are usually rich in chromatin ^{in the form of granules}; several nucleoli can generally be seen in each nucleus. The chromatic granules are ^{often} ~~at~~ ~~and~~, closely packed (& the nucleus is consequently deep-staining) in the smaller nuclei, whilst in the larger nuclei the ~~gran~~ chromatin-grains are ^{generally} separated more widely from one another & the nucleus contains more non-staining material.

~~I have rarely found nuclei which were~~

~~degenerating except in sporangia which were about to dehisce~~

In Botrychium Cardiff found that "as the spores commence to separate in the tetrad, the tapetal cytoplasm has entirely filled the sporangium + many of the nuclei have begun to disorganize, though they seem unusually persistent & many are found after the tetrad is fully formed. Later, when the spores are entirely separated + mature, the tapetum disappears." Dr. Helminthol

the tapetum + tapetal nuclei are evidently more persistent than Cardiff found ^{to be the case} in Botrychium. ⁽¹⁾ It has already been mentioned that the plasmatic membranes + many nuclei are still to be found between the spores which are quite or nearly mature & I have rarely found nuclei which were degenerating except in sporangia which were ^{almost ready to dehisce} ~~about to dehisce~~ ^{nearly mature}.

In such sporangia the majority of the nuclei

(1) Stevens also records much greater persistence of the nuclei in the Botrychium examined by him.

stained intensely & were ~~and~~ closely packed with chromatic granules whilst here & there a nucleus was seen in which the nuclear membrane had disappeared & the granules were becoming dispersed (Fig 13) Mitotic divisions of the tapetal nuclei were ^{at no time} ~~never~~ seen.

Cardiff records frequent amitotic divisions of the tapetal nuclei of Botrychium but Stevens was unable to confirm this observation.

In Helminthostachys I have found reason to believe that in the very early stages of sporangial development, ^{immediately after the} ~~at the time when the~~ tapetal membranes ^{have just} ~~are~~ disintegrated, the nuclei do multiply by direct division but I have never been able to satisfy myself that such divisions ^{take place} ~~occur~~ in older sporangia.

Passing ~~over~~ irregularities in outline which may sometimes lead to a more or less constricted shape ^{of the nucleus} occur but I do not find that these ^{over} ~~lead to the~~ result in the actual division of the nucleus: they

I do not wish to imply that Cardiff's observation of amitosis is necessarily correct. It is probable that such divisions ^{may} occur under particular conditions but that Stevens & myself have missed these. The single nucleus shown in Fig. 13 may be a stage of such a division but it stands alone in many hundreds of sections.

In Helminthostachys I have found reason to believe that in the early stages of sporangial development, immediately after the tapetal membranes have disintegrated, the nuclei do multiply by direct division but in older sporangia it is much more difficult to find any evidence of such divisions. ~~The~~ Irregularities in outline, which sometimes lead to a more or less constricted shape, ~~occure~~ not uncommonly occur but most of these are undoubtedly to be referred to those passing changes of form which are so frequently to be found in nuclei that are taking part in active metabolic processes. Occasionally these changes of form may actually lead to a division of the nucleus but in my material this is certainly rare. An isolated instance of such a division is shown in Fig 14. Very possibly the conditions which prevail at the time when the material is collected may ~~have~~^{exert} an influence

upon the tapetal nuclei & may ^{explain} ~~account for~~
~~the ^{different} different results which Cardiff &~~
 the differences which occur in the accounts
 of Cardiff & Steenens.

The principal features, therefore, which the tapetal nuclei
 plasmodium presents during the period of exospore
 growth are (1) an almost or quite complete
~~disappearance~~ disappearance of starch, (2) a gradual
 diminution of the finely vacuolar cytoplasm, &
 (3) the richly chromatic nuclei which often show
 irregularities of outline.

These features, I think, bear out the view ~~already~~
 already expressed that the tapetal plasmodium is the
 centre of metabolic activities in which a substance
 is elaborated from the raw materials contained in
 the tapetum. For reasons already stated we may
 further conclude that this substance is, directly
 or indirectly, employed in the growth of the
 spore-wall.
