About the Institute

The Hunt Institute for Botanical Documentation, a research division of Carnegie Mellon University, specializes in the history of botany and all aspects of plant science and serves the international scientific community through research and documentation. To this end, the Institute acquires and maintains authoritative collections of books, plant images, manuscripts, portraits and data files, and provides publications and other modes of information service. The Institute meets the reference needs of botanists, biologists, historians, conservationists, librarians, bibliographers and the public at large, especially those concerned with any aspect of the North American flora.

Hunt Institute was dedicated in 1961 as the Rachel McMasters Miller Hunt Botanical Library, an international center for bibliographical research and service in the interests of botany and horticulture, as well as a center for the study of all aspects of the history of the plant sciences. By 1971 the Library's activities had so diversified that the name was changed to Hunt Institute for Botanical Documentation. Growth in collections and research projects led to the establishment of four programmatic departments: Archives, Art, Bibliography and the Library.

On the Development of the Spores of *Riccia glauca*.

BY

RUDOLF BEER, F.L.S.

With Plates XXI and XXII.

THE principal facts in the development of the spores of *Riccia* have already been described by Leitgeb¹ and Strasburger². In the seventeen years which have elapsed since Strasburger's paper was written botanical microtechnique has, however, made such immense progress that it was thought desirable to subject these spores to a renewed investigation. Quite recently Garber³ has dealt with the life-history of *Ricciocarpus natans*, and Lewis⁴ with the embryology and development of *Riccia lutescens* and *R. crystallina*, but neither of these authors has described the spore or the development of its membranes.

Lewis's observations show that *Riccia lutescens* is merely a terrestrial form of *Ricciocarpus natans*, and he believes that the differences which exist in the structure of the thallus and the arrangement of the sexual organs are not sufficiently marked to justify the genetic separation of *Ricciocarpus* from *Riccia*. He accordingly drops the genus *Ricciocarpus* altogether and includes *Ricciocarpus natans* among the Ricciae.

The material for the present study was fixed in strong and medium chrom-acetic mixtures (Chamberlain's formulae), strong Flemming's solution and in alcohol and acetic acid mixture. Of these the stronger chrom-acetic fluid proved the most satisfactory, but excellent results were also obtained with the alcohol and acetic mixture.

I will begin my account with the fertilization of the egg-cell. The general character of this process is shown in Pl. XXII, Fig. 28, from which it will be seen that it closely resembles the fertilization of *Riccia* (*Ricciocarpus*) *natans* as described by Garber. My photograph also shows that the shrinkage

² Strasburger, Ueber das Wachsthum vegetabilischer Zellhäute. Histologische Beiträge, Heft 2, 1889, pp. 104-111.

³ Garber, The Life-history of *Ricciocarpus natans*. Bot. Gazette, vol. xxxvii, 1904, pp. 161-77.

⁴ Lewis, The Embryology and Development of *Riccia lutescens* and *Riccia crystallina*. Bot. Gazette, vol. xli, 1906, pp. 109-38.

of the egg-cell is far less than is usually figured, and in this point I am again in agreement with Garber's statements. The first division of the fertilized egg-cell is usually obliquely transverse (Fig. 32). The succeeding divisions have been so frequently described that I need not recapitulate them here. They result in a mass of sporogenous tissue surrounded by a single layer of sterile wall-cells, the whole being enclosed within a two-layered calyptra. The young spore-mother-cells are at first separated from one another by extremely delicate membranes (Fig. 29). These stain, often deeply, with bismarck brown, but I am unable to get a decided reaction in them with ruthenium red, whilst with calcium-chloride-iodine and chlor-zinc-iodine they colour yellow but show no signs of containing cellulose.

The cell contains a quantity of starch which is especially abundant round the nucleus. Upon the primary walls which separate the spore-mother-cells from one another a secondary and, later, a tertiary thickening layer is deposited (Pl. XXI, Fig. 5). Both layers give the reaction of cellulose as well as those of pectose, but the tertiary thickening layer (viz. the one in immediate juxtaposition with the protoplast) stains the more deeply with pectic reagents.

The protoplast surrounded by the tertiary thickening layer now rounds itself off and becomes separated from the primary mother-cell membrane. The secondary thickening layer, which has become more or less mucilaginous in consistency, sometimes separates completely from the primary walls and then forms a well defined layer surrounding the protoplast (Figs. 5, 9, 31). At other times, on the contrary, it remains partly adherent to the primary wall and in that case it becomes drawn out into a number of strands bridging over the gap between the rounded protoplast and the primary wall. The latter condition is represented in Fig. 6, and it will be observed that my drawing closely resembles Leitgeb's Fig. 3, Taf. II. Leitgeb, however, believed that the space between the primary wall and the protoplast was occupied by a homogeneous mucilage, and that the strands of material which both he and I have figured are composed of food-materials diffusing in from the outside. In my preparations it is quite certain that no homogeneous mucilage occupies the space between protoplast and primary wall; moreover the strands of material stretching across this space give cellulose and pectose reactions exactly corresponding with those obtained in the secondary thickening layer (e.g. of Fig. 5 where the cells are still partly united).

It should be mentioned that the condition represented in Fig. 6 is no doubt somewhat exaggerated by the reagents used. The measurement of the spore-mother-cells shown in Figs. 30 and 9 gave an average diameter of about 46μ , whilst that of the cells in the sporangia from which Fig. 6 was drawn was only 40μ . I believe, therefore, that the effect is somewhat heightened by the reagents employed, but I see no reason to conclude that

the condition is entirely due to them. During the isolation of the spore-mother-cells from one another the sporangial cavity enlarged considerably. Taking the measurements from the periphery of the outer of the two layers of the archegonial wall the diameter of the cavity at such a stage as that shown in Fig. 29 is about 240μ , whilst when the mother-cells are rounding off (as in Fig. 30) it has increased to about 300 or 345μ .

Garber and Lewis have both described a large amount of nutritive material which fills the space between the mother-cells and which is secreted by the surrounding cells. In my preparation of *Riccia glauca* I have seen nothing of this material¹.

The rounded mother-cells now proceed to divide. The following description is based upon the study of preparations which have been stained with Heidenhain's haematoxylin, either alone or with a light counter stain with bismarck brown. The large nucleus of the spore-mother-cell just before the commencement of division contains a conspicuous, deep-staining nucleolus and a number of delicate linin fibres which have little affinity for dyes (Figs. 1 and 2). In these features the resting nucleus of the sporogenous cells of *Riccia glauca* differs from the description given by Lewis for the two species which he has studied. He found the nuclear cavity to be occupied by a linin network upon which the scanty chromatin is irregularly scattered; moreover he states that no nucleolus was to be seen. I have examined a large series of sections of sporangia containing mother-cells at all stages up to their mitotic division, but I have never observed a nucleus which contained a reticulum such as Lewis figures, nor one which was without a nucleolus. In the case of *Riccia glauca*, therefore, we can be certain that no such non-nucleolated, reticular resting stage occurs.

It may also be added that the resting condition of the vegetative nuclei of the thallus of *Riccia glauca* agrees essentially with what I have described above in the case of the sporogenous cells.

The nucleolus in nearly all cases has a lobular outline (Fig. 1) and I believe that this is due to the fact that the nucleolus is not a homogeneous body, but is composed of a number of small chromatic masses or granules held together by a common matrix. These granules are usually so closely crowded together in the nuclei of the sporogenous cells that it is not easy to see their separate individuality. In a few cases, however, the nucleolus was actually seen to be composed of distinct granule-like bodies which had become rather more widely separated from one another than usual by the action of the reagents employed or through the pressure of the microtome knife (Fig. 2)². In the vegetative nuclei at the growing apex of the thallus the constitution of the nucleolus can be much more readily determined when

¹ See Garber, l. c., Plate X, Fig. 37.

² Compare also Fig. 16, in which the separate chromatin granules of the earlier stages of division are massing together to form one body.

differentiation with the iron-alum has been carried to the right point. It can then be seen that these nucleoli consist of a faintly stained matrix in which are embedded a number of intensely black bodies (Fig. 3).

Compound nucleoli of a similar character occur in the nuclei of the Musci. In the spermatogenous cells of *Atrichum undulatum* the nucleoli can be quite clearly seen to consist of a lightly coloured matrix containing a number of chromatic particles¹.

In several sporangia I have found that the linin threads tend to become more or less massed towards one side of the nuclear cavity (Fig. 7). This may correspond to a synapsis stage, although I am not prepared to say how far reagents are responsible for its production in the present case.

Following this condition we find that a much more deeply staining and thicker thread has been developed, which traverses the nuclear cavity in a number of coils or loops (Fig. 8). This is unquestionably the spirem-thread, and it differs radically from the short thread described by Lewis in *Riccia crystallina*². The thread can often be followed continuously for a considerable distance, and I believe that it forms an unbroken filament.

In well stained preparations the spirem-thread shows very beautifully an alternation of deeply coloured bodies (chromomeres) with lighter areas (Fig. 8).

It is very probable that the increased amount of chromatic material which the thread contains at the spirem stage has been derived from the nucleolus and most likely at the expense of the chromatic granules which this body encloses. I have unfortunately been unable to find the stages in the division of the sporogenous cells which lie between the establishment of the spirem and the arrangement of the chromosomes at the equator of the spindle (Fig. 10). In the spermatogenous cells of the antheridium, however, in which a spirem is also developed, the actual segmentation of this thread into the chromosomes could be followed, and it was clearly seen that during this process the nucleolus became more and more inconspicuous. By the time the chromosomes are fully established the nucleolus has been lost sight of altogether.

Both Garber and Lewis have recorded four chromosomes in *Riccia* (*Ricciocarpus*) *natans*, and Lewis found the same number in *Riccia crystallina*. In *Riccia glauca* the number of chromosomes is higher than this, and I have been able to determine with certainty that the reduced number is either seven or eight (Figs. 9 and 11). The distribution of the chromosomes to

¹ I should like to take this opportunity of correcting an error which I made in a previous note upon 'The chromosomes of *Funaria hygrometrica*' (New Phyt., vol. ii, 1903, p. 166). I there stated that the number of chromosomes which appeared in the first division of the spore-mother-cells was four. Since this was written I have examined properly fixed material of several mosses (*Funaria hygrometrica*, *Atrichum undulatum*, *Mnium hornum*, *Polytrichum juniperinum*) and I have found that in all cases the number of chromosomes is far higher than I formerly supposed.

² Compare Lewis's Plate VII, Fig. 25, with my drawing of this stage.

the daughter-nuclei is shown in Fig. 11. On first reaching the apex of the spindle the chromosomes are crowded closely together (Fig. 12). Soon, however, a nuclear membrane is formed and the chromosomes proceed to open out.

During the earlier stages of the telophase a number of chromatic bodies can be seen distributed upon the linin, and these bodies are no doubt the derivatives of the chromosomes (Figs. 13 and 14). At a later stage the scattered chromatin bodies have come together to form a single lobular nucleolus, whilst linin fibres, containing little or no stainable material, extend through the nuclear cavity (Figs. 15 and 16). The spindle during the metaphase and anaphase of the division is a comparatively narrow structure. A conspicuous cell-plate is developed at the equator of the spindle (Fig. 12). During the telophase of division the spindle shortens and broadens out very considerably and the cell-plate becomes correspondingly broader (Fig. 14).

A membrane is developed at the equator of the spindle, no doubt between the split halves of the cell-plate, although the splitting of the plate could not be followed here on account of its great delicacy. This membrane, which stains rather deeply with bismarck-brown, does not at first reach right across the cell (Fig. 15), but by the time that the nuclei are again dividing it has almost or quite reached the periphery of the cell (Fig. 17). After a short interval of rest the nuclei enter upon the second meiotic division.

At the conclusion of this division cell-membranes are formed which complete the division of the mother-cell into the four daughter-cells, which are conveniently, if incorrectly¹, called the special-mother-cells. These membranes, separating the special-mother-cells from one another, give both cellulose and pectose reactions, as do the secondary and tertiary thickening layers of the mother-cell which still form the peripheral envelope of the tetrad group.

It may be mentioned here that during the development of these septa a large proportion of the starch of the cell is seen to be aggregated in their neighbourhood (Figs. 17 and 18).

The special-mother-cell walls do not long remain in this condition, but secondary thickening layers are soon deposited upon the inner surfaces of the thin pectose-cellulose membranes (Fig. 19).

These thickening layers have an uneven outline, forming the papillate projections into the interior of the cell, which previous writers have fully described. Their reactions show that they consist of callose apparently unaccompanied by any other substance. They colour deeply in corallin-soda, in aniline-blue, in congo-red and in naphthol-black². On the other

¹ Miss Benson, New Phytologist, vol. iv, 1905, p. 96.

² I have elsewhere dealt with the specific staining properties of naphthol-black (see Beihefte zum Bot. Centralblatt, Bd. XIX, Abt. I, Heft 2, 1905, p. 289).

hand, calcium-chloride-iodine and chlor-zinc-iodine do not stain these layers. In ruthenium-red and bismarck-brown they assume a faint colour, but I do not think that this is sufficiently marked to indicate the presence of pectose in these layers.

The membranes which first limited the cells of the tetrad from one another before the thickening layers were deposited can now be seen as middle lamellae running through the midst of the callose layers, and as a peripheral covering to the entire tetrad. These primary membranes continue to colour distinctly pink-violet with calcium-chloride-iodine solution and deeply red with ruthenium-red, whilst callose reagents leave them unstained. They still possess, therefore, the unchanged pectose-cellulose constitution which they had in the first place.

It may be mentioned here that Leitgeb¹ reached very different results on these points. During the earlier stages following the thickening of the special-mother-cell walls he could distinguish no middle lamella, and only after the first spore-wall has made its appearance 'differenziert sich in den Scheidewänden die Mittellamelle.' This is certainly incorrect, for the middle lamellae are nothing but the original pectose-cellulose septa of the unthickened special-mother-cell wall which maintain their individuality throughout.

Leitgeb further states, on the same page, that in aniline-blue an outer layer of the special-mother-cell wall colours deep blue whilst the inner parts, corresponding to our secondary thickening layers, only assume a yellowish tinge in this solution. If this were the case we should have to conclude that the composition of the special-mother-cell wall is very different from that which I have described above, but I have so repeatedly assured myself that the behaviour of this wall towards aniline-blue is precisely the opposite to what Leitgeb found and, moreover, this has been so thoroughly supported by the reactions of the wall with other reagents, that there cannot be the slightest doubt of the correctness of my conclusions.

The occurrence of callose in the special-mother-cell walls of one of the Hepaticae is of interest since in no other member of the Archegoniata series which I have examined is that substance to be found in this position; and it is only when we reach the Gymnosperms and Angiosperms that callose can again be seen surrounding the pollen-tetrads².

It is very probable that callose occurs constantly in the special-mother-cell walls of the liverworts since some observations which I am making upon the spore-development of *Anthoceros laevis* have shown that callose is also present in the tetrad walls of this plant.

In the Musci the special-mother-cell walls contain pectose and cellulose,

¹ Leitgeb, l. c., p. 43.

² In all Gymnosperms and Angiosperms which I have examined callose formed the only demonstrable constituent of the special-mother-cell wall.

whilst in the leptosporangiate ferns, the Ophioglossaceae and in the ligulate and eligulate Lycopodiums these walls contain either cellulose and pectose or pectose alone, but no trace of callose¹. On another occasion² I have referred to the manner of origin of callose in the special-mother-cell walls of *Oenothera*, and the same remarks apply with equal force to the callose of *Riccia*. In the present case it is impossible to suppose that the callose can have arisen from the transformation of cellulose, since none of this substance precedes the callose nor can any cellulose be seen to disappear from other neighbouring membranes. We must conclude, therefore, that the callose in the tetrad walls of *Riccia* is formed directly as such by the protoplast.

The tetrad-group grows in size from about 60 μ to about 75 to 85 μ in diameter and then the first spore-wall³ is formed round each of the four cells. The question of the origin of this layer constitutes one of the chief points of difference between the accounts of Leitgeb and Strasburger. The former writer was convinced that this wall is a transformation product of the innermost layers of the special-mother-cell wall, whilst Strasburger is equally positive that it is a new formation of the protoplast which has no relation to the special-mother-cell wall.

I have spent no little time upon this question and the only conclusion which I am able to reach is a negative one. After carefully considering the grounds upon which Leitgeb and Strasburger based their respective views I am forced to conclude that these were insufficient to prove the case either one way or the other. Leitgeb lays the greatest weight upon the firm adhesion which exists between the special-mother-cell wall and the first spore-wall. After treating the spores with various reagents (chlor-zinc-iodine or a not too strong mixture of chromic and sulphuric acids) he found that the first spore-wall remained firmly fixed to the special-mother-cell wall, although this was greatly swollen.

An argument based upon the adhesion of two layers to one another cannot, however, be accepted as proof of their common origin. Cases are known in which two layers are firmly united but which have unquestionably been separately deposited by the protoplast. Thus Fitting⁴ has referred to the special-mother-cell wall and the secondary thickening layer of the spore-mother-cell wall of *Isotetes* which adhere closely together but which are independently developed. The special-mother-cell wall and the very young pollen-wall of the Phanerogams furnish another example of two layers which

¹ I have, unfortunately, had no opportunity of examining the special-mother-cell walls of *Equisetum* as yet.

² Beer, l. c., p. 290.

³ In the following account I have avoided the terms exospore or perispore and speak only of first and second spore-membranes. Since, however, the innermost layer of the spore is certainly homologous with the endospore of other plants I have used that name for it.

⁴ Fitting, H., Bot. Zeit., Bd. 58, 1900, p. 126.

are often at first inseparably united, but which nevertheless have a distinct origin. In his examination of *Riccia* Strasburger found that by bursting the special-mother-cell wall by means of pressure he was able to separate the spore-protoplast, surrounded by the first spore-wall, from the special-mother-cell wall. Moreover, he states that the folds of the first spore-wall never quite reach to the summits of the indentations in the special-mother-cell wall¹. If this were actually the case it would, as Strasburger clearly saw, form strong evidence in favour of the independent origin of the two layers. My own preparations, however, do not confirm Strasburger in this respect. Wherever the section is accurately longitudinal (as regards the fold of membrane and the indentation) it can be distinctly seen that the first spore-wall lines the indentation in the special-mother-cell wall to its very apex. Where, however, the section has cut the fold of the first spore-wall somewhat obliquely the true relations of this fold to the indentation are not always at once clear.

From what has been said above it will be seen that the evidence which we possess is entirely inconclusive and that neither Leitgeb nor Strasburger were justified by the facts in assuming a definite position.

A study of the microchemical reactions of this wall furnishes no assistance in deciding this question. The whole behaviour of the wall indicates that it is cuticularized from a very early period; whether there is a basis of cellulose, callose, or pectose preceding or underlying the cuticularization was not apparent from any of my experiments.

It may be mentioned here that after treating sections of older spores with a mixture of chromic and sulphuric acids and then (after washing) adding chlor-zinc-iodine it can be seen that the first spore-wall has a rather densely laminated structure (Figs. 24 and 25).

Not long after the first spore-wall has been formed a deposit of mucilaginous substance can be seen at the equatorial rim² of the spore (Fig. 20). As Leitgeb correctly stated, this mucilage has the same chemical and physical properties as the secondary thickening layers of the special-mother-cell wall; that is to say it is composed of callose. Leitgeb further supposed that this mucilage was derived from the special-mother-cell wall, a portion of which wandered through the first spore-wall at the equatorial region. The first spore-wall is, however, always continuous and never interrupted at any spot, as Leitgeb thought was sometimes the case (Figs. 20, 21). Strasburger considered the mucilage to be a part of the first spore-wall; his chief reason for doing so was that he found that this wall and the mucilage were not sharply marked off from one another at the equatorial rim. I find that the mucilage is formed later than the first spore-wall, that the callose

¹ Strasburger, l. c., p. 109.

² Leitgeb called this equatorial rim a 'Saum,' whilst Strasburger wrote of 'einem äquatorialen Flügel, das heisst einem an der Grenze von Rücken- und Bauchfläche verlaufenden Saum.'

mucilage is always sharply defined from the delicate spore-wall which has quite different staining properties, and that it is not difficult to separate the one from the other by means of reagents. I regard the mucilage, therefore, as a new formation which has no relation either to the special-mother-cell wall or to the first spore-wall.

The older writers believed that this mucilage formed a continuous layer over the inner face of the first spore-wall. I do not find this to be the case.

Over the ventral surfaces of older spores, in which the second spore-wall has been developed, it can be seen that the two membranes lie closely against one another without any mucilage between them (Fig. 21). Over the dorsal surface of the spore the two layers of the wall are indeed frequently separated from one another and then the space between them appears to be, at least partly, occupied by a mucilage. How far this separation between the two walls of the spore over the dorsal surface is a normal feature of their structure is, however, difficult to say. In older spores the mucilage at the equatorial rim has again become absorbed and can no longer be seen.

At first this mucilage is limited internally only by the plasma membrane of the protoplast, which is pushed inwards at the equatorial seam by the plug of mucilage (Fig. 20). Before long, however, the spore-protoplast develops a new wall within the first one, and this then forms a flattened internal boundary to the mucilage at the rim of the spore (Fig. 21). This second spore-wall is a cuticularized structure almost from the commencement. At the very first, however, it is probably composed of uncuticularized pectose-cellulose, for when it is just discernible it stains more deeply with bismarck-brown than is usual with cuticularized membranes, and, moreover, the lamellae which are subsequently added to its thickness unquestionably have, at first, a pectose-cellulose constitution.

During the earliest stages of its existence the second spore-wall appears, even under high magnifications, as a perfectly homogeneous layer, but in spores which are a little older it has become considerably thicker and then a dark line can be seen traversing the middle of this wall and dividing it into an inner and an outer part (Figs. 22, 35). This dark line grows in thickness with the age of the spore until it not infrequently becomes a thick layer which stains intensely black with Heidenhain's haematoxylin and forms the most conspicuous feature in the spore-wall (Fig. 26). It is not easy to assure oneself of the real nature of this dark layer, but after comparing together a large number of spores I am led to the conclusion that this layer most probably only represents a gap which is formed between two sets of lamellae and which becomes occupied by some dark-coloured, stainable material. This view seems to me to be supported by the fact that the dark layer varies in the time and in the position of its appearance. Some-

times it is discernible at a very early stage in the history of the second spore-wall. Sometimes the spore has become much older and the second spore-wall has become quite a thick structure before any signs of this layer can be seen¹. Again its appearance is sometimes nearer, sometimes further away from the outer periphery of the spore-wall. In preparations which have been treated with a mixture of chromic and sulphuric acids a separation of two sets of lamellae can often be seen in the second spore-wall with an evident gap between them. Further evidence is given by a study of older spores in which a similar but much narrower black band can usually be seen between the inner boundary of the second spore-wall and the endospore (Fig. 26). What the nature and origin of the substance which occupies this space may be is quite unknown. It does not seem unlikely, however, although I can bring forward no proof for the view, that the dark substance which collects in the gap of the spore-wall is the material which colours brown the older spore-walls throughout their thickness.

Most instructive preparations of the spore-wall at the middle periods of development may be obtained by treating sections with a mixture of chromic and sulphuric acids, washing and then examining them in chlor-zinc-iodine or calcium-chloride-iodine. The first spore-wall is coloured yellow and shows a densely laminated structure. Within this wall lies the second spore-wall. The outer portion of this wall is seen to be composed of loosely arranged lamellae which sometimes lie closely against the first spore-wall but which have usually become separated from it by the action of the reagent (Figs. 24, 25). The inner portion of the wall, which is generally separated from the loose lamellae by a gap, has a homogeneous appearance and no lamellae can be distinguished in it. If the action of the acids has been carried to the right point it can be seen that the inner part of this internal layer of the second spore-wall gives beautiful cellulose reactions with the iodine reagents. The band of cellulose is considerably thicker on the dorsal surface of the spore, whilst cuticularization had become more complete over the ventral surfaces. Congo-red in dilute solution also colours the cellulose areas a deep red.

Although the inner portion of the second spore-wall has a homogeneous appearance, even after the action of reagents, it is nevertheless really built up of successive lamellae.

During the development of the spore this inner region of the second spore-wall grows very considerably in thickness, and the sections show with unmistakable clearness that this growth is due to the deposition of a series of lamellae upon one another. The newest lamella is formed by the protoplast of the spore in the most intimate attachment with the plasmatic membrane. By plasmolysing the protoplast this lamella is usually at the same time separated from the walls of the spore and the contracted proto-

¹ The late appearance of this dark layer is shown in Fig. 23.

plast can then be seen to be surrounded by a thin layer which gives cellulose-pectose reactions (Fig. 36). It may be said, therefore, that in the formation of the second spore-wall the first lamellae which are deposited are comparatively loosely arranged together (outer region of second spore-wall), whilst the later ones become so firmly united that the lamellose nature of this portion of the wall becomes obscured (inner region of second spore-wall). It is these two regions of the wall—the loosely and the densely laminated areas respectively—which become more or less separated from one another by the interpolation of the dark material which was mentioned above.

The endospore is formed comparatively late in the development of the spore. It gives the reactions of cellulose and pectose, and it is usually separated from the second spore-wall by a narrow space occupied by dark material similar to that which occurs in the more conspicuous gap between the two layers of the second spore-wall (Fig. 26). In spores which are nearly or quite mature the walls are deeply coloured brown and have become much denser and in consequence thinner. The lamellated structure of the wall is now obscured. Heated to redness on platinum foil with a drop of concentrated sulphuric acid the entire spore dissolves without leaving a silica skeleton behind.

Nothing has been said above of the nutrition of the spore or of the sources of the material for the growth of its membranes, so that a few words upon this subject must be added here. That the protoplast of the spore is itself actively concerned in the growth of the membranes which surround it can scarcely be doubted. The new lamellae which are added to the second spore-wall are formed, as we have seen, in the most intimate union with the plasmatic membrane; the nucleus of the spore also presents an appearance which strongly suggests that it is participating in metabolic activities.

Unlike the usual resting nucleus of *Riccia glauca*, to which I have already referred, the chromatin is not confined to the nucleolus, but is also distributed along a rather thick filament which strongly recalls the spirem-thread of the dividing nucleus (Fig. 27 a, 27 b). It is difficult to decide whether this thread forms one continuous structure or not.

As the spore grows older and its walls become thickened we find that, although the thread long maintains its spirem-like arrangement, it gradually stains less and less deeply with the haematoxylin (Fig. 27 c). Somewhat similar spirem-nuclei have been described in various animal cells. Thus the well-known case of the salivary glands of *Chironomus* larvae, studied by Balbiani, may be recalled, or the ovarian eggs of *Triton taeniatus*, in which Born found a spirem-stage to precede a more diffuse arrangement of the chromatin. In most of the cases already known in which the chromatin is distributed through the nucleus in this manner, we are dealing with cells

which exhibit considerable metabolic activity, and we may probably infer that some relation exists between the spirem-arrangement and the cell activity. A similar relation between the peculiar nuclear structure and cell-metabolism no doubt also occurs in the developing spores of *Riccia glauca*. The actual material which is used by the protoplast in forming and adding to the spore-walls must be derived from without the spore. The reserve material and cytoplasm of the spore suffer very little diminution during development, and if these are drawn upon to furnish material for the growth of the membranes, this loss is at once fully compensated by the arrival of new material from without. The starch-contents of a spore at about the middle period of its development is shown in Fig. 34, and almost precisely the same appearance is presented by the spore-protoplast in the preceding and succeeding stages.

Both the sterile parietal layers of the sporangium and the inner layer of the calyptra¹ degenerate and yield some material which is no doubt employed in the growth of the spore-walls. Neither of these layers is, however, rich in substance (see Figs. 4, 29), and I scarcely think it is possible that their degeneration can furnish all the material required for the very considerable growth undergone by the membranes. Most probably this source is supplemented by material which is assimilated by the vegetative cells of the thallus, and which diffuses into the sporophyte in a state of solution. After the first spore-wall has been formed, and during all the earlier periods of the growth of the second spore-wall, a mucilage is constantly present in the sporangium between the spore-tetrads (Fig. 33). The origin and significance of this mucilage are, however, somewhat obscure. It is certainly not the material secreted by the surrounding cells of the thallus, since not a trace of mucilage can be detected in any of these. The callose special-mother-cell walls, which for some time continue to surround the spore-tetrads, gradually disappear, but there is no evidence to show that their substance makes any contribution to the sporangial mucilage which, moreover, gives none of the reactions of callose. Two sources remain, both or either of which may be responsible for the sporangial mucilage. In the first place the degeneration of the parietal cells of the sporangium and of the inner archegonial layer may contribute to the formation of the mucilage. In that case it still remains to be explained how it is that the parietal cells have degenerated some time before the mucilage can be seen, whilst some remains of the inner archegonial cells can frequently still be detected after the mucilage has again become absorbed. Secondly, the degeneration of the primary mother-cell walls and of their thickening layers, which are both lost sight of about this time, may give rise to part or all of the sporangial mucilage. A difficulty in the way of at once accepting this view of the origin of the

¹ The outer layer of the calyptra persists to a very late stage.

mucilage lies in the fact that whilst the secondary thickening layer of the mother-cell walls gives both cellulose and pectose reactions, I have been unable to demonstrate the presence of cellulose in the mucilage.

It must, therefore, remain uncertain for the present to what extent the mucilage in the sporangium possesses a nutritive value.

By the time that the second spore-wall has become differentiated into the two sets of lamellae (with the dark layer separating them from one another) the mucilage has become very scanty, and soon after it entirely disappears.

SUMMARY.

1. Fertilization of the egg-cell of *Riccia glauca* corresponds essentially with Garber's description of this process in *Riccia* (*Ricciocarpus*) *natans*.

2. The spore-mother-cells are at first separated from one another by extremely delicate membranes, which stain deeply with bismarck-brown but in which no cellulose could be demonstrated.

3. Upon these primary spore-mother-cell walls secondary and, later, tertiary thickening layers are deposited. Both these layers give pectose-cellulose reactions.

4. The protoplast, surrounded by the tertiary thickening layer, now rounds itself off. The secondary thickening layer, which becomes more or less mucilaginous, sometimes separates completely from the primary wall and then forms an external envelope to the mother-cell, whilst at other times it still remains partly adherent to the primary wall, and in that case it becomes drawn out into strands of mucilage bridging over the space between primary wall and tertiary thickening layer. The latter condition corresponds to Leitgeb's description of this stage, but he erroneously interpreted the mucilage-strands as nutritive material passing into the mother-cell.

5. In *Riccia glauca* no demonstrable nutritive material was found between the isolated mother-cells such as Garber and Lewis have described in the case of *Riccia* (*Ricciocarpus*) *natans*.

6. The resting nucleus of the spore-mother-cell contains a large, deep-staining nucleolus and a number of delicate linin fibres. No non-nucleolated, reticular resting nucleus, as described by Lewis in *Riccia* (*Ricciocarpus*) *natans* and *R. crystallina*, was found in *Riccia glauca*.

7. The nucleolus of the nucleus of *Riccia glauca* appears to be a compound structure consisting of a number of deeply chromatic masses or granules embedded in a matrix which stains only faintly.

8. A long and well-marked spirem-thread occurs in the prophase of the division of the spore-mother-cell. This differs radically from the short thread described and figured by Lewis in *Riccia crystallina*.

9. The reduced number of chromosomes in *Riccia glauca* is either seven or eight, but it could not be decided with certainty between these two numbers.

It will be noted that this number is considerably higher than that (four) recorded by Garber and Lewis in *Riccia (Ricciocarpus) natans* and *R. crystallina*.

10. In the telophase of the division a number of chromatic bodies, which are no doubt derivatives of the chromosomes, are distributed upon the linin fibres. Subsequently these scattered bodies aggregate together to form the lobular nucleolus of the resting nucleus.

11. The membrane, which is formed between the daughter-cells resulting from the first division of the mother-cell, does not at first extend to the periphery of the cell.

12. At the conclusion of the second mitotic division the special-mother-cells are separated from one another by delicate membranes which have a pectose-cellulose composition.

13. Upon these primary special-mother-cell walls secondary thickening layers are deposited which give the reactions of callose. This callose is directly deposited as such by the protoplast, and is not a transformation product of cellulose.

14. The first spore-wall is a cuticularized structure from a very early period. No decisive data could be found to determine whether this wall is derived from the transformation of the innermost lamellae of the special-mother-cell wall or whether it is a new formation directly due to the secretory activity of the protoplast. It was shown that the arguments brought forward by previous writers are insufficient to prove the case either one way or the other.

15. Within the first spore-wall at the equatorial rim a plug of mucilage is deposited. This mucilage, which gives the reactions of callose, has no direct relation either to the thickening layers of the special-mother-cell wall (as Leitgeb supposed) or to the first spore-wall (as Strasburger supposed). It is a new and independent formation.

16. The second spore-wall is next formed within the first wall. It is cuticularized from a very early time, but there is reason to believe that previous to its cuticularization it reacts as a pectose-cellulose membrane.

17. At first the second spore-wall appears to be quite homogeneous, but subsequently it can be seen to be composed of three parts:—

- (i) an external loosely laminated region ;
- (ii) a layer of dark-coloured material ; and
- (iii) an internal densely laminated region.

The dark-coloured material appears to have been interpolated into a space which forms between the two laminated regions of the wall.

18. The endospore, which is formed late in the development of the

spore, gives the reactions of pectose and cellulose. It is often separated from the second spore-wall by a very thin band of dark-coloured material similar to that which occurs in the gap between the two regions of the second spore-wall.

19. No silica could be detected in the spore-membranes.

20. The protoplast of the spore is actively concerned in the growth of the membranes which surround it. The intimate union which exists between each new lamella, which is being added to the wall, and the protoplast in itself indicates this fact, whilst the curious spirem-like structure of the spore-nucleus, resembling that of certain animal cells, also suggests the occurrence of active metabolic processes in the cell.

21. The actual material necessary for the growth of the spore-walls is partly derived from the breaking down of the parietal cells of the sporangium and of the inner layer of the calyptra. This source is most probably supplemented by material which is assimilated by the vegetative cells of the thallus, and which diffuses into the sporophyte in a state of solution.

22. After the first spore-wall has been formed, and during all the earlier periods of the growth of the second spore-wall, a quantity of mucilage is constantly present in the sporangium between the spore-tetrads. The origin and significance of this mucilage are, however, still somewhat obscure. The various possibilities of the case are discussed in the body of the paper.

In conclusion I should like to express my thanks to Professor J. B. Farmer, F.R.S., for kindly examining my sections and for offering several valuable suggestions.

"On the development of the Spores of Riccia glauca"

The principal facts in the development of the Spores of Riccia have already been described by Leitgeb⁽¹⁾ & Strasburger⁽²⁾. In the seventeen years which have elapsed since Strasburger's paper was written botanical microtechnique ^{however, made} ~~has~~ such immense strides forward that it was thought desirable to ~~re~~ subject these Spores to a renewed investigation. Quite recently Garber⁽³⁾ has dealt with the life-history of Ricciocarpus natans & Lewis⁽⁴⁾ with the embryology & development of Riccia lutescens & R. crystallina but neither of these authors ^{has} ~~have~~ dealt with the Spore or the development of its membranes.

(1) Leitgeb "Ueber Bau und Entwicklung der Sporenhäute".
Graz, 1884 pp. 39-49.

(2) Strasburger "Ueber das Wachsthum Vegetabilischer Zellhäute"
Histologische Beiträge Heft 2. 1889. pp. 104-111.

(3) Garber "The Life History of Ricciocarpus natans"
Bot. Gazette Vol XXXVII. 1904. p.p. 161-177.

(4) Lewis "The Embryology & Development of Riccia lutescens & Riccia crystallina"
Bot. Gazette Vol XLI. 1906. p.p. 109-138.

Lewis' observations show that Riccia lutescens is merely a terrestrial form of Ricciocarpus natans & he believes that the differences which exist in the structure of the thallus & the arrangement of the sexual organs are not sufficiently marked to justify the genetic separation of Ricciocarpus from Riccia. He accordingly drops the genus Ricciocarpus altogether & includes Ricciocarpus natans among the Ricciae.

The material for the present study was fixed in strong & medium chrom-acetic mixtures (Chamberlain's formulae), strong Flemming's solution & in alcohol & acetic acid mixture.

Of these the stronger chrom-acetic fluid proved the most satisfactory but excellent results were also obtained with the alcohol & acetic mixture.

I will begin my account with the fertilization of the egg-cell. The general character of this process is shown in Fig 28. from which it will be seen that it closely resembles the fertilization of the ^{Riccia} (Ricciocarpus) nataans as described by Garber¹¹. My photograph ~~will~~ also shows that the shrinkage of the egg-cell is far less than is usually figured & in this point ^{I am again} ~~Riccia~~ in agreement with Garber's statements regarding Ricciocarpus. The first division of the fertilised egg-cells is usually obliquely transverse (Fig 32). The succeeding divisions have been so frequently described that I need not recapitulate them here. They result in a mass of sporogenous tissue surrounded by a single layer of sterile wall-cells, the whole being enclosed within a two layered calyptra.

(1) Garber "The Life History of Ricciocarpus nataans"
Bot Gazette March 1904 Vol XXXVII pp 161-177

at first
 The young spore-mother-cells are separated from one another by extremely delicate membranes (Fig. 29). These stain, often deeply, with bismarck brown but I was unable to get a decided reaction in them with ruthenium red ~~nor~~ did they whilst with Calcium-chloride-iodine + chlor-zinc-iodine they colour yellow but ~~give none of the cellular reactions~~. Show no signs of containing cellulose.

Upon the cell contains a quantity of starch which is especially abundant round the nucleus. Upon the primary walls which separate the spore-mother-cells from one another a secondary & later, a tertiary thickening layer is deposited (Fig. 5). Both layers give the reactions of cellulose as well as ^{those} of pectose but the tertiary thickening layer (viz the one in immediate juxtaposition with the protoplast) stains ^{the} more deeply with pectic reagents.

The ~~protoplast~~ protoplast surrounded by the tertiary

thickening layer now rounds itself off & becomes separated from the primary matter-cell membrane. The secondary thickening,

layer which has become more or less mucilaginous in consistency, sometimes separates completely from the primary walls & then forms a well defined layer surrounding the protoplast (Figs 5, 9, 31). ~~which~~ At other times, ^{on the contrary,} it ~~becomes drawn out~~ ~~partly adherent~~

remains partly adherent to the primary wall & ^{that} ~~in which~~ case it becomes drawn out into a

number of strands bridging over the gap between the rounded protoplast & the primary wall.

The latter condition ~~of things~~ is represented in Fig 6. & it will be observed that my drawing closely resembles Leitgeb's Fig 3 Taf. II. Leitgeb, however, believed that the space between the primary wall & the protoplast was occupied by a homogeneous mucilage & that the strands of material ~~extending~~ which both

he & I have figured are really composed of food-materials diffusing in from the outside. In my preparations it is quite certain that no homogenous mucilage occupies the space between protoplast & primary wall; moreover the strands of material stretching across this space give cellulose & pectose reactions exactly corresponding with those obtained in the secondary thickening layer (e.g. of Fig 5 ³) where the cells are still ^{partly} united).

It should be mentioned that the condition represented in Fig 6 is no doubt somewhat exaggerated by the reagents used. The measurement of the spore-matter-cells shown in Figs 3 & 9 gave an average diameter of about 46μ whilst that of the cells in the sporangia from which Fig 6 was drawn was only 40μ . I believe, therefore, that ~~that~~ the effect is somewhat heightened by the reagents employed but I see no reason to ~~conclude~~ ^{conclude} that ~~the condition~~ ^{the condition} is entirely caused by them due to them.

During the isolation of the spore-mother-cells from one another the sporencial cavity ~~two~~ ^{enlarges} ~~increased~~ considerably. ~~in size~~. Taking the measurements from the ~~outer~~ periphery of the outer of the two layers of the archegonial wall the diameter ^{of the cavity} at such a stage as that shown in Fig 29 is about 240μ whilst when the mother-cells are rounding off (as in Fig 30) ~~the diameter is also roughly~~ ^{it has increased to about} between $300 + 345 \mu$.

Garber & Lewis ^{best} have described a

large amount of nutritive material which fills the space between the mother-cells & which is secreted by the surrounding cells. In my preparations of Riccia glauca I have seen nothing of this material. ⁽¹⁾

The rounded mother-cells now proceed to divide. The following description is based upon ^{the study of} preparations which ^{have} ~~had~~ been stained with Heidenhain's haematoxylin, either alone or with a

(1) See Garber l.c. Plate X Fig. 37

light counter stain with bismarck brown.

The large nucleus of the Spore-mother-cell just before the commencement of division contains a conspicuous, deep-staining nucleolus + a number of delicate linen fibres which have little affinity for dyes ^(figs 1+2). In these features

the resting nucleus of the ~~sporangial~~ sporogenous cells of Riccia glauca differ from the description given by Lewis ^{for the} ~~for the case of the~~ ^{two species which he} ~~examined~~. ^{He} found the nuclear cavity to be occupied by a linen network upon which the scanty chromatin ~~was~~ ^{moreover he states that} is irregularly scattered; ~~what~~ ^{no} nucleolus ^{to be} was ^{seen}.

I have ^{examined} a large series of sections ~~of~~ of sporangia ^{containing} ~~with~~ the mother-cells at all stages up to their ^{maturation} division but I have never observed a nucleus which contained a reticulum such as Lewis figures nor one which was without a nucleolus. In the case of Riccia glauca, therefore, we can be certain

that no such non-nucleolated, reticular resting stage occurs.

It may also be added that the resting condition of the vegetative nuclei of the thallus of R. glauca agrees ~~at~~ essentially in ~~structure~~ with what I have described above in the case of the sporogenous cells.

The nucleolus in nearly all cases has a lobular outline ^(Fig 1)  I believe that this is due to the fact that the nucleolus is not a ~~homogeneous~~ body but is composed of a number of small masses or granules held together by a common matrix. These granules are usually so closely crowded together in the nuclei of the sporogenous cells that it is not easy to see their separate individuality. In a few cases, however, the nucleolus was actually seen to be composed of distinct granule-like bodies which had become rather more widely separated from one another than usual.

by the action of the reagents employed or through the pressure of the microtome knife (Fig 2) ⁽¹⁾
 In the vegetative nuclei at the growing apex of the thallus the constitution of the nucleolus can be much more readily determined when differentiation with the Iron-alum has been carried to the right

Digitized by Hunt Institute for Botanical Documentation

(1) compare also Fig 16 in which the ^{separate} chromatin granules ~~are~~ of the earlier stages of division are massing together to form one body.

point. It can then be seen that these nucleoli consist of a faintly stained matrix in which are embedded ~~of intensely black~~ a number of intensely black bodies (Fig 3)

Compound nucleoli of a similar character occur in the nuclei of the Musci. In the Spermatogenous cells of Atrichum undulatum the nucleoli can be quite clearly seen to consist of a lightly coloured matrix containing a number of chromatic particles⁽¹⁾

(1) I should like to take this opportunity of correcting an error which I made in a previous note upon the "The chromosomes of Funaria hygrometrica (New Phyt. Vol II 1903 p.166.) I there stated that the number of chromosomes which appeared in the first division of the Spore-mother-cells was four. Since this was written I have examined properly fixed material of several mosses (Funaria hygrometrica, Atrichum undulatum, Mnium hornum, Polytrichum juniperum) & I have found that in all cases the number of chromosomes is far higher than I formerly supposed. I have not yet succeeded in counting the number of chromosomes with accuracy in any species but

In several sporengia I have found the linen threads tend to become more or less massed towards one side of the nuclear cavity (Fig 7) This ^{may} ~~probably~~ correspond to a synapsis stage although I am not prepared to say how far reagents are responsible for its production in the present case.

Following this condition we find that a much more deeply staining & thicker thread has been developed which traverses the nuclear cavity ~~again~~ in a number of coils or loops (Fig 8)

This is unquestionably the Spirem-thread & it differs radically from the Short thread described by Lewis in Riccia crystallina.⁽¹⁾

The thread can often be followed continuously for a considerable distance & I believe that it forms an unbroken filament.

In well stained preparations the Spirem-thread shows very beautifully an alternation of

(1) Compare Lewis' Plate VII Fig 35 with my drawing of this stage.

deeply coloured bodies, with lighter areas (Fig 8)
~~It may be noticed~~

It is very probable that the increased amount of chromatic material which the ~~of~~ thread contains ^{at} when the Spirem ^{stage} ~~has become~~ established ~~has been distributed~~

has been derived from the nucleolus + most likely at the expense of the chromatic granules which this body encloses. I have unfortunately been ^{un}able to find the stages in the division of

the spermatogenous cells which lie between the

establishment of the Spirem + the arrangement of the chromosomes at the Equator of the Spindle (Fig 10).
 In the spermatogenous cells of the antheridium,

however, in which a Spirem is also developed, the actual segmentation of ~~it was seen like~~ this thread ~~became segmented~~ ^{could be followed & it was clearly seen} into the chromosomes ^{that during this}

process the nucleolus became more & more inconspicuous. By the time the chromosomes are ^{fully} established the nucleolus ^{has} ~~had~~ been lost sight of altogether.

~~The chromosomes are either 7 or 8 in number.~~

~~The chromosomes are either seven or eight in number.~~

Both Garber & Lewis have recorded four chromosomes in Riccia (Ricciocarpha) natans & Lewis found the same number in

R. crystallina. In Riccia glauca

the number of chromosomes is certainly higher than this & I have been able to determine with certainty that the reduced number is either seven or eight (Figs 9 & 11)

of the chromosomes
The distribution ^{of the chromosomes} to the daughter nuclei is shown in Fig. 11

. On first reaching the apex of the spindle the chromosomes are crowded closely together (Fig 12). Soon, however, a nuclear membrane is formed & the chromosomes proceed to open out.

During the earlier stages of the telophase a number of chromatic bodies can be seen distributed upon the linen & these bodies are ~~for~~ no doubt the derivatives of the

Chromosomes (Figs 13+14)

At a later stage

the scattered chromatin bodies have come together to form a ~~lob~~ single lobular nucleus (~~Fig 13~~) whilst linear fibres, containing little or no stainable material, extend through the nuclear cavity (Figs 15+16)

The spindle during the metaphase + anaphase of the division is a comparatively narrow structure. A conspicuous cell-plate is developed at the equator of the spindle (Fig 12)

During the telophase of division the spindle shortens + broadens out very considerably + the cell plate becomes correspondingly broader (Fig 14).

A ~~cell plate~~ very conspicuous cell-plate is developed at the Equator of the Spindle.

During the telophase of division the Spindle shortens & broadens very considerably (Fig. 7).

& the cell-plate becomes correspondingly broader. ~~The splitting of the cell-plate~~

~~could not be observed on a thin membrane is developed account of the small size of the structure.~~

A membrane is developed at the Equator of the Spindle, ^{no doubt} ~~presumably~~ between the split halves of the cell plate although the splitting of the plate could not be followed ^{here} on account of its ~~small~~ great delicacy.

This membrane, which stains ^{rather} deeply with bismarck brown, does not at first reach right across the cell ^(Fig. 15) but by the time that the nuclei are again dividing it has almost ^(Fig. 17) or quite reached the periphery of the cell ~~Fig. 17~~.

~~It has been able to make only very few observations upon the second division of the~~

After a short interval of rest the nuclei enter upon ~~undergo~~ the second mitotic division.

~~Mother-cell + I will only ^{state} mention here that~~
~~the chromosomes again number 8.~~

At the conclusion of this division cell-membranes
 are formed which ^{complete the division of} ~~divide~~ the mother-cell into
 the four daughter-cells which are conveniently,
 if incorrectly⁽¹⁾, called the Special-mother-cells.
 These membranes, separating ~~+ bounding~~ the
 Special-mother-cells ^{from one another,} give both cellulose
 + pectose reactions ^{as does the secondary + tertiary} like the ~~broken~~ Secondary
 thickening layers of the mother-cell which still
 form the peripheral envelope of the tetrad
 group.

It may be mentioned here that ^{during} the development
 of these young septa ~~but~~ at the conclusion
 both of the first + second divisions of the
 a large proportion of the ^{of the cell} starch ^{is} seen to be aggregated
 in their neighbourhood. (Figs 17 + 18)

The special-mother-cell walls do not long
 remain in this condition but secondary

(1) Miss Benson New Phytologist Vol IV 1905 p 96

thickening layers are soon deposited upon the inner surfaces of the thin pectose-cellulose membranes. (Fig 19)

These thickening layers have an uneven outline, forming the papillate projections into the interior of the cell which previous writers have fully described.

Their reactions show that they consist of callose apparently unaccompanied by any other substance. They ~~could~~ colour deeply in corallin-soda, in aniline-blue, in congo-red + in naphthol black. On the other hand calcium-chloride-iodine & chlor-zinc-iodine do not stain these layers. In ruthenium-red + bismerch-brown they assume a faint colour but I do not think that this is sufficiently marked to indicate the presence of pectose in these layers.

Rutheium red, bismarck brown + similar dyes
colour the walls very faintly so that it is possible that a
trace of pectose occurs in them as well as in the cell walls. 19

The membranes which first limited the cells of the
tetrad from one another before the thickening layers
were deposited can now be seen as middle
lamellae running through the midst of the callose
layers & as a peripheral covering to the
entire tetrad. These primary membranes continue
to colour distinctly pink-violet with calcium-
chloride-iodine solution & deeply red with
ruthenium red ~~thus showing~~ whilst
callose reagents leave them unstained.
They still ^{remain} ~~constitute~~ therefore, ^{unchanged} the pectose-
cellulose ^{constitution which} ~~which~~ they ~~possessed~~ had in the
first place.

It may be mentioned here that Leitgeb
reached very different results on these
points. During ~~the~~ the earlier stages ^{following} ~~after~~ the
~~thickening layers~~ ~~had been~~ special-mother-cell
~~had thickened its walls~~ ^{ing of the special-mother-cell walls} he could distinguish
no middle lamella & only after the first

Spore-wall has made its appearance "differenziert
sich in den Scheidewänden die Mittellamelle"

This is certainly incorrect for ~~the original~~
~~septa of the special-matter cell can be~~
the middle lamellae are nothing but the original
pectose-cellulose septa of the unthickened
special-matter-cell wall which maintain
their individuality throughout.

Leitzger further states on the same page that
in aniline-blue an outer layer of the
special-matter-cell wall colours deep blue

whilst the inner parts, corresponding to
our ~~the~~ secondary thickening layers, only assume
a yellowish tinge in this solution

If this were the case, ^{he should have to conclude that} the composition of
the special-matter-cell wall ^{is} ~~would be the~~
very different ^{from that which} ~~reverse of what~~ I have ^{described} written above, but

I have so repeatedly assured myself that the
behaviour of this wall towards ~~an~~ aniline-
blue is precisely the opposite to what

Moreover, Liebig found ⁺ this has been so thoroughly supported by the reactions of the wall with other reagents that ~~I have not the slightest~~ ^{there cannot be} doubt ~~as to the~~ of the correctness of my conclusions.

The occurrence of callose in the special-matter-cell walls of ^{one of the Hepaticae.} ~~the Hepaticae~~ is of ~~some~~ interest since in no other member of the Archegoniate series ~~have I found~~ which I have examined ^{is} ~~was~~ that substance to be found in ^{this position} ~~these walls~~ + it is only when we reach the Gymnosperms + Angiosperms that ~~the pollen-tetrads are seen to be surrounded by callose walls.~~ callose can again be seen surrounding the pollen-tetrads. ⁽¹⁾

It is very probable that callose occurs constantly in the special-matter-cells ~~of~~ walls of the liverworts since some observations which I am making upon the spore-development

(1) In all Gymnosperms + Angiosperms which I have examined callose ~~is~~ ^{is} formed ^{in the special-matter-cell wall.} (the only demonstrable constituent of)

of Anthoceros laevis ^{has} have shown that callose ^{is also} present in the tetrad walls of ~~oocysts~~ this plant. ~~also~~

In the Musci the special-mother-cell walls contain ~~only~~ pectose & cellulose whilst in the leptosporangiate ferns, the Ophioglossaceae & in the ligulate & eligulate Lycopodiums these walls contain either cellulose & pectose or pectose alone but no trace of callose.⁽¹⁾ On another occasion⁽²⁾ I have referred to the manner of origin of callose in the special-mother-cell walls of Oenothera & the same remarks apply with equal force to the callose of Riccia. In the present case it is impossible to suppose that the callose can have arisen from the transformation of ~~pre-existing~~ cellulose since none of this substance precedes the callose ^{nor} can ~~the~~ ^{any cellulose} ~~be seen~~ ^{to} disappear from other neighbouring membranes. We must conclude, therefore, that ^{the} callose in

I am greatly indebted to Miss Agnes Robertson D.Sc. for a ~~special~~ ^{special} mother-cell walls of Quercus as yet.
(1) ~~Special~~ ^{special} mother-cell walls of Quercus as yet.
(2) Beer l.c. p. 290

the tetrad walls of Riccia is formed directly as such by the protoplast.

The tetrad-group grows in size from about 60μ in diameter to ^{about} 75 to 85μ in ^{diameter} ~~the~~ the first spore-wall ⁽¹⁾ is formed round each of ~~the~~ ^{following} the four cells. The question of the origin of this layer ^{constitutes} ~~formed~~ one of the chief points of difference between the accounts of Leitgeb & Strasburger. The former ^{writer} was convinced that this wall ~~is~~ is a transformation product of the innermost layers of the special-mother-cell wall whilst Strasburger is equally positive that it is a new formation of the protoplast which has no relation to the special-mother-cell wall.

I have spent no little time & ~~trouble~~ upon this question & the only conclusion which I am able to reach is a negative one. After carefully considering the grounds upon which Leitgeb & Strasburger based their

(1) In the following account I have avoided the terms exospore or perispore & speak only of first & second spore-membranes. Since, however, the ~~inner~~ the innermost layer of the spore is certainly homologous with the endospore of other plants I have used that name for it.

respective views I am forced to conclude that these were insufficient to prove the case either ^{or} way or the other. Seitze~~ls~~ lays the greatest weight upon the firm adhesion which exists between the special-matter-cell wall + the first spore-wall ~~but cases of~~

~~as intimate union between ^{two} layers of are known in which these layers certainly had a different origin.~~

After treating the spores with various reagents (chlor - zinc - iodine or a not too strong ~~solution~~ mixture of chromic & Sulphuric acids) he found that the

~~greatly swollen special-matter cell wall separated from the spore protoplast still firmly fixed to the~~

first spore-wall ~~still~~ ^{remained} firmly fixed to the ~~greatly swollen special-matter-cell wall,~~

~~separated from the protoplast.~~ although this was greatly swollen.

An argument based upon the adhesion of

two layers to one another cannot, ^{however,} be accepted as proof of their common origin. Cases are known in which two layers are firmly united but which have unquestionably been separately deposited by the protoplast. Thus Fitting⁽¹⁾ has referred to the ~~instance of the~~ special-mother-cell wall + the secondary thickening layer of the ^{Spore-}mother-cell wall of *Isoetes* ~~and~~ which adhere closely together but which are independently ~~for~~ developed.

The Special-mother-cell wall + the pollen wall of ~~Phanerogams~~ the Phanerogams

furnishes another ~~and~~ example of two ~~members~~ layers which ^{are often} at first ~~are~~ inseparably united but which ^{nevertheless} have a distinct origin.

In his examination of the ^{Riccia} ~~Spores~~ Strasburger found that by bursting the Special-mother cell wall ^{by means of} ~~through the application of~~ pressure he was able to separate the Spore-^{protoplast} ~~protoplast~~.

(1) Fitting H Bot. Zeit. Bd 58 1900 p. 126

, surrounded by the first spore-wall, from the Special-mother-cell wall. Moreover he states that the folds of the first spore-wall never quite reach to the summits of the indentations in the Special-mother-cell walls. (") If this were actually the case it would, as Strasburger clearly saw, form strong evidence in favour of the independent origin of the two layers. My own preparations, however, do not confirm Strasburger in this respect. Whenever the section is accurately longitudinal (as regards the fold of membrane & the indentation) it can be distinctly seen that the first spore-wall lines the indentation in the Special-mother-cell wall to its very apex. Where, however, the section has cut the fold of the first spore-wall somewhat obliquely the true relations of this fold to the indentation are not always at once clear.

formed a deposit of mucilaginous substance can be seen ~~especially~~ at the equatorial rim⁽¹⁾ of the spore (Fig. 20). As Litzsch correctly stated this mucilage has the same chemical & physical properties as the ~~checkered~~ secondary thickening layers of the special-mother-cell wall; that is to say it is composed of callose. Litzsch further supposed that this mucilage was derived from the special-mother-cell wall, a portion of which ~~wandres~~ ^{passes} through the first spore-wall at the equatorial region. The first spore wall is, however, always continuous & never interrupted at ~~the~~ any spot as Litzsch thought was. Sometimes the case (Fig. 20, 21). Strasburger ^{considered} ~~reckoned~~ the mucilage ^{to be a} ~~part~~ part of the first spore-wall; his chief reason for doing so was that he ~~found the separation between the two~~ ^{distinction} found that this wall & the mucilage were not

(1) Litzsch called this equatorial rim a "Saum" whilst Strasburger wrote of "einem ~~aspekt~~ äquatorialen Flügel, des Leists einen an der Grenze von Rücken- und Bauchfläche verlaufenden Saum"

sharply marked off from one another at the equatorial rim. I find that the mucilage is formed ^{later than} ~~separately & later & separately~~ from the first spore wall, that the callose mucilage is always sharply defined from the delicate spore-wall which has quite different staining properties & that it is not difficult to separate the one from the other by means of ^{reagents}. I regard the mucilage, therefore, as a new formation which has no relation either to the special-mother-cell wall or to the first spore-wall.

I have been able to trace the mucilage, as a very delicate layer, for ^{only a very little} ~~some~~ distance ~~but~~ beyond the equatorial rim & in older spores, in which a second ~~spore-wall~~ ^{often} has been formed, a mucilage, apparently, ^{often} separates the two walls over the dorsal surface of the spore. ~~but~~ ^{nevertheless} I cannot feel any by no means sure that this mucilage ~~also~~ really forms a continuous layer lining the whole inner

The older writers believed that this mucilage formed a continuous layer over the inner face of the first spore-wall. I do not find this to be the case, ~~however~~.

Over the ventral surfaces of older spores, in which the second spore-wall has been developed, it can be seen that the two membranes lie closely against one another without any mucilage between them (Fig 21). Over the dorsal surface of the spore the two layers of the wall are ^{indeed} frequently separated from one another & then the space between them appears to be, at least partly, occupied by a mucilage. How far this separation between the two walls of the spore over the dorsal surface is a normal feature of their structure, ~~whether the mucilage is~~ ^{is, however} is difficult to say. ~~even if it naturally occurs it is by no means certain that in the mucilage which one finds there~~ is. In older spores the mucilage at the equatorial rim has again become absorbed & can no longer be seen.

- (1) The second spore-wall seems, however, not to reach the apex of the folds of the first spore-wall over the dorsal surface of the spore even in those preparations which ~~have been~~ ^{are} shown the best fixation & here ^{it is} most probably some mucilage really occurs.

face of the first spore-wall. On the ventral surfaces of ^{slightly} older spores the first & second spore-walls, even under high magnifications, appear to lie immediately against one another. It is possible, however, that even at this comparatively early stage the mucilage may already have become absorbed ^{at this spot} & the two spore-walls be thus brought together.

At first this mucilage is limited internally only by the plasma membrane of the protoplast ^{which is pushed inwards at the equatorial} seam by the plug of mucilage. (Fig 20) Before long, however, the spore-protoplast develops a new wall within the first one & this then forms a flattened internal boundary to the mucilage at the rim of the spore (Fig 21). ~~Leitzsch believed that the second spore wall~~
 This ^{second spore-} wall is a cuticularised structure ~~from a~~ commencement. ~~When it is~~ almost from the ~~first~~ ^{commencement}. ~~just discernable~~ it stains rather deeply.

At the very first, however, it ^{is may} probably ^{be} ~~consists~~ ^{is} composed of uncuticularised pectose-cellulose for ^{when} ~~when~~ it is just discernable it stains ^{more} deeply with bismarck brown than is usual with cuticularised membranes ^{moreover,} & ^{the} lamellae which are subsequently added to its thickness unquestionably have, at first, a pectose-cellulose constitution.

During the earliest stages of its existence

At ^{first} ~~first~~ the Second Spore-wall appears, even under high magnifications, as a perfectly homogeneous layer but in Spores which are a little older it has become considerably thicker & then a dark line can be seen traversing the middle of this wall & dividing

it into an inner + an outer part (Figs 22, 35)

This dark line grows in thickness with the age of the Spore until it not infrequently ^{becomes} ~~forms~~ a thick layer which stains intensely black with Heidenhain's haematoxylin + forms ^(fig 26) the most conspicuous feature in the Spore-wall.

It is not easy to assure oneself of the real nature of ~~this~~ dark layer but ~~after comparing~~

~~together all my sections~~ after comparing together
I am led to the conclusion ~~that~~

a large number of spores ^{which} are ~~convinced~~

~~are inclined to think~~ (most probably) represents a gap
that this layer only a space which is

formed between two sets of lamellae & which becomes occupied by some dark coloured, stainable material. This view seems to me to be

material. ^{supported}
~~base~~ ^{out} by the fact that the dark layer
varies in the time + in the position of its
appearance. Sometimes it is discernable

at a very ~~very~~ early stage in the history of
the Second Spore-wall ^(Vogel) Sometimes the Spore
has become much older & the Second Spore-

wall has become quite a thick structure ^{without} ~~before~~
 any signs of this layer ^{being} ~~can be~~ seen⁽¹⁾. Again
 its ~~position~~ ^{usually} ~~appearance~~ appearance is
 sometimes nearer, sometimes further away from the
 outer periphery of the second spore-wall.

In preparations which have been treated with
 a mixture of chromic + sulphuric acids a
 separation of two sets of lamellae ^{often} can be
 seen in the second spore-wall with an
 evident gap between them. Further evidence

is given by a study of older spores in which a
 similar but much narrower black band
 can ^{usually} ~~sometimes~~ be seen between the inner boundary
 of the second spore-wall + the endospore ^(Fig. 26).

What the nature + origin of the substance
 which occupies this space may be is quite
 unknown. ~~I do not seem implicitly shown,~~
 although I can bring forward no proof ~~of~~
 for the view, that the dark material in the
 gaps of the spore-wall ~~are~~ ~~are~~ is the

(1) The late appearance of this dark layer is shown in Fig. 23.

brown

Substance which colours the older spore-walls throughout their thickness.

Most instructive preparations of the spore-wall ~~available~~ ^{at} the middle periods of development may be obtained by treating sections with a mixture of chromic + sulphuric acids, washing + then examining them in chlor-zinc-iodine or calcium-chloride-iodine. The first spore-wall is coloured yellow & shows a densely laminated structure. Within this wall lies the second spore-wall. The outer portion of this wall is seen to be composed of loosely arranged lamellae which sometimes lie closely against the ~~older~~ first spore-wall but which have usually become separated from it by the action of the reagent. (Figs 24, 25) The inner portion of the wall, ~~thinner~~ ^{generally} which is ~~loosely~~ separated from the loose lamellae by a gap, ~~and~~ has ^a homogeneous appearance & in which no lamellae can be distinguished in it. Its most

If the action of the acids has been carried to the right point it can be seen that the inner ~~part~~ ^{part} ~~is~~ ^{is} ~~not~~ ^{not} ~~infrequently~~ ^{infrequently} ~~observed~~ ^{observed} the entire inner part of this internal layer of the second spore-wall gives beautiful cellular reactions with the iodine reagents. The band of cellulose ~~is~~ ^{is} considerably thicker ~~on~~ ^{on} the dorsal surface of the spore whilst ~~cuticularisation~~ ^{cuticularisation} had become more complete over the ventral surfaces. Congo-red in dilute solution also colours the cellulose areas a deep red.

Although the inner portion of the second spore-wall has a homogeneous appearance, even after the action of reagents, it is nevertheless really ~~solid~~ ^{solid} ~~fact~~ ^{fact} built up of successive lamellae.

appearance of the wall	from the time of the first
grows very considerably in thickness	this inner region
not difficult to obtain	preparations which

During the development of the spore this inner region of the second spore-wall grows very considerably in thickness & the sections show with unmistakable clearness that this growth is due to the deposition of a series of lamellae upon one another. The newest lamella is formed by the protoplast of the spore in the most intimate attachment with the plasmatic membrane. By plasmolysing the protoplast this lamella is at the same time ^{usually} separated from the walls of the spore & the contracted protoplast can then be seen to be surrounded by a thin layer (Fig 36). It may be said, therefore, that in the formation of the second spore-wall the first lamellae which are deposited are comparatively loosely arranged together (outer region of second spore-wall) whilst the later ones become so firmly united that the lamellous nature of this portion of the wall becomes obscured (inner region of second spore-wall). It is these two β regions of the wall — the loosely & the densely laminated areas respectively — which become more or less separated from one

another by the interpolation of the dark material which was mentioned above.

The endospore is formed comparatively late in the development of the spore. It gives the reactions of cellulose + pectose & ^{it} is ~~for~~ usually separated from the second spore-wall by a narrow ~~gap~~ space occupied by ~~the a similar~~ dark material similar to that which occurs in the more conspicuous gap between ~~first + second spore~~ the two layers of the second spore-wall (Fig 26).

In spores which are nearly or quite mature the walls are deeply coloured & have become much denser & in consequence thinner. The lamellated structure of the wall is now obscured. Heated to redness on platinum foil with a drop of concentrated sulphuric acid the entire spore dissolves without leaving a silica skeleton behind.

~~In the foregoing description of the spore membranes I have refrained from using the terms~~
~~The exospore or perispore since these~~ ^{names} ~~are~~ ^{not}

Nothing has been said above of the nutrition of the spore or of the sources of the material for the growth of ^{its} membranes so that a few words upon this subject must be added here.

That the protoplast of the spore is itself actively concerned in the growth of the membranes which surround it can scarcely be doubted.

The new lamellae which are added to the second spore-wall are formed, ^{as we have seen,} in the most intimate union with the plasmatic membrane; the nucleus of the spore also presents an appearance which is strongly ~~suggestive~~ suggests that it is participating in metabolic activities.

Unlike the usual resting nucleus of *Riccia glauca*, to which I have already referred, ~~to~~ the chromatin is not confined to the nucleolus but is also distributed along a rather thick ~~thread~~ ^{filament} which strongly recalls the ~~spiral~~ ^{spiral} coiled thread of the spore spirem-thread of the dividing nucleus (Fig. 27a, b, c). It is difficult

to decide whether this thread forms one continuous structure or not.

At first As the spore grows older & its walls become thickened we find that although the thread long maintains its spirem-like arrangement it gradually stains less & less deeply with the haematoxylin (Fig 27a c)

Somewhat similar spirem-nuclei have been described in various animal cells. Thus

the well known case of the salivary glands of Chironomus - larvae, studied by Balbiani,

may be recalled or the ovarian eggs of Triton taeniatus in which Born found

a spirem-stage to precede a more diffuse arrangement of the chromatin. In most of

the cases ^{already known} in which ~~the~~ the chromatin is distributed through the nucleus in this manner

we are dealing with cells which exhibit considerable metabolic activity & we may probably infer that ~~and similar~~ some relation

Exists between the Sporem - arrangement + the cell activity. A similar relation between the peculiar nuclear structure + cell-metabolism no doubt also occurs in the developing spores of Riccia glauca.

The actual material which is used by the protoplast in forming + adding to the spore-walls must be derived from without the spore. The reserve material + cytoplasm of the spore suffer very little diminution during development + if these are drawn upon to furnish material for the growth of the membranes this loss is at once fully compensated by the arrival of new material from without. The starch-contents of a spore at about the middle period of its development is shown in Fig 34 + almost precisely the same appearance is presented by the spore-protoplast in the preceding + succeeding stages.

Both the sterile parietal layers of the sporangium + the inner layer of the calyptra "degenerate + yield some material which is no doubt employed in the

The outer calyp layer of the calyptra persists to a very late stage.

growth of the spore-^{walls} ~~membrane~~. Neither, of these
layers ^{is}, however, rich in substance + (See Figs 4, 39)

Scarcely think it is possible that their degeneration
can furnish ~~sufficient~~ ^{all the} material ^{required} for the very
considerable growth ^{undergone by} of the membranes. Very most
probably this source is supplemented by the
material which is assimilated by the vegetative
cells of the thallus + which diffuses into the
~~sporophyte~~ sporophyte in a state of solution.

After the first spore-wall has been formed + during
all the earlier periods of the growth of the second
spore-wall a mucilage is constantly present ~~between~~
in the Sporangium between the spore-tetrads (Fig 33)

The origin + significance of this mucilage are,
^{however} somewhat obscure. It is certainly not the
^{material} secreted by the surrounding cells of the thallus
since not a trace of mucilage can be detected in
any of these. The cellose special-mother-cell
walls, which for some time continue to surround
the spore-tetrads, gradually disappear but there

is no evidence to show that this substance makes any contribution to the sporangial mucilage which, moreover, gives none of the reactions of callose. ~~There are two~~ Two sources remain, both or either of which may be responsible for the sporangial mucilage. In the first place the degeneration of the parietal & inner archegonial layers may contribute to the formation of the mucilage. In that case it still remains to be explained how it is that the parietal cells have degenerated some time before the mucilage can be seen whilst ^{some} remains of the inner archegonial cells can frequently still ~~be~~ detected after the mucilage has again become absorbed. Secondly the degeneration of the primary mother-cell walls & of their thickening layers, ^{both of} which are lost sight of about this time, may give rise to part or all of the sporangial mucilage. ~~Therefore~~ A difficulty ^{in the way of} at once accepting this ^{view of the} origin of the

lies in the fact
 mucilage is that whilst the secondary thickening
 layer of the mother-cell walls gives both
 cellulose & pectone reactions I have been
 unable to demonstrate the presence of cellulose
 in the mucilage.

It must ^{therefore,} remain uncertain for the present ^{to what extent} ~~whether the~~
 the mucilage in the Sporangium possesses a
 nutritive value. ~~or no.~~

By the time that the second spore-wall has become
 differentiated into the two sets of lamellae (with the
 dark layer separating them from one another) the
 mucilage has become very scanty & soon after it
 entirely disappears.

In conclusion I ^{should like to} ~~must~~ express my thanks to
 Professor J. B. Farmer F.R.S. for kindly
 examining my sections & for offering several
 valuable suggestions.

Summary of Riccia glauca

- (1) Fertilisation of the egg-cell is essentially ^{Gardner's} ~~similar~~ corresponds to the description of this process in Riccia (Ricciocarpus) notans.
~~The early divisions of the fertilised egg-cell can now be found to~~
- (2) The Spore-mother-cells are at first separated from one another by extremely delicate membranes which ^{stain deeply with} ~~give~~ some of the pectic reactions (e.g. with bisulphate brown) but ~~which~~ in which no cellulose can be demonstrated.
- (3) Upon the primary Spore-mother-cell walls a secondary + later, a tertiary thickening layers are deposited. Both these layers give ~~both~~ pectic + cellulose reactions.
- (4) The protoplast, surrounded by the tertiary thickening layer now rounds itself off. The secondary thickening layer ^{which} ^{is} ^{impermeable} becomes ^{impermeable} mucilaginous & sometimes separates completely from the primary wall & then forms an external envelope to the mother cell whilst at other times it still

partly adheres to the primary wall & in that case it ^{becomes drawn out into} ~~for appears as~~ strands of mucilage bridging over the space between primary wall & ^{protoplasm} ~~mucilage~~ cell. The latter condition I corresponds to Leitzel's description of this stage but he ^{erroneously} interpreted the mucilage ^{strand} as nutritive material passing into the mucilage cell.

- (5) In Riccia glauca no ^{stainable} demonstrable nutritive material, ~~and~~ is ~~occasionally~~ could be ~~demonstrated~~ with the strands found between ~~any of the~~ the isolated mucilage cells ~~in any of my preparations~~ such as Garber & Lewis have described in Riccia (Ricciocarpos) natans.

- (6) The resting nucleus of the spore-mucilage cell contains a ~~comp~~ large, deep-staining nucleolus & a number of delicate linear fibres. It ~~is~~ non-nucleolated, reticular, resting nucleus, ~~as~~ as ~~to~~ was described in by Lewis in Riccia lutescens & R. crystallina, Riccia (Ricciocarpos) natans & R. crystallina, was found in Riccia glauca.

- (7) The nucleolus of ~~the~~ the nuclei of Ricea glauca appears to be a compound structure consisting of a number of deeply chromatic ~~bodies~~ ^{masses} or granules embedded in a matrix which ~~has only little affinity for dyes~~ ^{stains only faintly}.
- (8) A ^{long &} well marked spore ~~stage~~ occurs in the mitosis of the spore-mother-cell. ~~which~~

This differs entirely from the short thread described & figured by Lewis in Ricea

ory Stallenia

- (9) The number of chromosomes in R. glauca ^{the division of the spore-mother cells of} ~~is~~ ^{is} ~~without doubt~~ found to be either seven or eight, ~~but~~ ^{but} it ~~could not be decided~~ ^{was uncertain} ~~between these numbers.~~ ~~Could not be decided with certainty which of these numbers was the correct one.~~ ~~but it could not be decided with certainty which of these two numbers is the correct one.~~ This number is the present plant differs in the number of its chromosomes from Ricea (Ricocarpus) valens & R. crystallina, in the meiotic divisions of which Garton & Lewis have recorded only ~~of~~ four chromosomes.
- ~~It will be noted that this number is considerably higher than~~ ⁽⁴⁾ ~~the~~ ^{the} recorded of Garton & Lewis in Ricea (Ricocarpus) valens & R. crystallina.

- (10) In the telophase of ^{the} division a number of chromatic bodies, ~~as such~~ which are no doubt derivations of the chromosomes, are distributed upon the lumen. Subsequently these scattered bodies aggregate together to form the lobular nucleolus.
- (11) The membrane which is formed between the daughter-cells resulting from the first division of the mother cell does not at first reach the periphery of the cell.
- (12) At the conclusion of the second mitotic division the Special-mother-cells are separated from one another by delicate membrane which ~~form the~~ ^{are then} ~~composed~~ ^{reaction} of pectin + cellulose composition.
- (13) Upon these primary Special-mother-cell walls secondary thickening layers are deposited which give the reactions of callose. This
- (14) Callose is ~~certainly a new formation~~ ^{directly} deposited as such by the protoplast + cannot be a transformation product of cellulose.

(14) The first spore-wall is a cuticularized structure
from a very early period. It could not be
decided whether it ~~was~~ ^{is} derived from the transposition
of the innermost lamellae of the special mother
cell wall or whether it is a new formation
~~directly derived from~~ ^{directly due to} the secretory activity of the
protoplast. The arguments ~~presented~~ brought
forward by previous writers are insufficient
to prove the case either one way or the other.

(15) Within the first spore wall at the Equatorial
line a plug of mucilage is deposited.
This mucilage, which gives the reactions of
callose, has no direct relation either to the
thickening layers of the
"Special-mother-cell-wall" or to the first
spore wall.

(16) The second ~~spore~~ ^{spore} wall is next formed within
the first wall. This is cuticularized ~~from~~ ^{from a} ~~very early time~~ ^{very early time}
~~from the commencement~~ but there is reason to believe
that ~~the~~ ^{previous} cuticularization is ~~preceded~~ by it
reacts as a pectone-cellulose membrane.

- (14) At first ~~the wall~~ the second spore-wall is apparently homogeneous but subsequently it can be seen to consist of three parts viz. ~~an internal & external~~ (1) a-
external loosely laminated region (2) a
layer of dark-colored material (3) an
internal densely laminated region.

The ^{laminated} dark-coloured material appears to be subsequently interpolated into a space which forms between the two laminated regions of the wall.

- (18) The endospore ^{which} is a formed late in the development of the spore ~~with~~ given the reactions of pectin & cellulose. It is often separated from the second spore wall by a ^{very} thin band of ~~deep~~ dark-coloured material similar to that which occurs in the gap between the two regions of the second spore wall.
